Two other tests exist based on detection of human antibodies in serum or plasma: indirect immunofluorescent assay kit to test specific IgG antibodies against antigens located on the cell wall surface of the mycelium of *Candida albicans* CAGTA (*Candida albicans* germ tube antibody) IFA IgG, Vircell Microbiologist® and indirect chemiluminescent immunoassay (CAGTA VirClia®). These tests have low sensitivity, which limits their use alone despite their high specificity. Some studies have shown that the association of CAGTA tests with the detection of BDG or anti-mannan antigen could improve diagnostic performance for invasive candidiasis (León et al., 2012; Martínez-Jiménez et al., 2014, 2016; Pini et al., 2019; Zaragoza et al., 2009).

Antifungal susceptibility testing (AFST)

Although the first role of antifungal susceptibility testing (AFST) is to provide information on minimal inhibitory concentration to antifungal drugs and the chances of success of initiated treatment, clinical breakpoints are not well-established for every *Candida* species. Epidemiological breakpoints may be relevant to track antifungal resistance and changes in epidemiology. Currently two methods are standardized for *Candida* spp., broth dilution and disk diffusion. ESCMID guidelines published in 2012 recommend the testing of all *Candida* isolates found in the blood stream and other deep sites (Cuenca-Estrella et al., 2012). The Infectious Diseases Society of America (IDSA) made the same statement in 2016, and recommended the testing of azoles, at least (Lortholary et al., 2012; Pappas et al., 2016). An echinocandin susceptibility test is also recommended for *C. glabrata* and *C. parapsilosis* (Bassetti et al., 2020; Berkow et al., 2020).

Promising technologies for the diagnosis of invasive candidiasis

With the same idea of reaching a faster and more precise diagnosis, diagnostic methods using immunohistochemistry, in situ hybridization and mass spectrometry are being developed and some have already been validated by the FDA.

MALDI-TOF-MS is a technique using mass spectrometry allowing rapid identification (10–30 min) of pathogens from a vial of positive blood culture (Griffin and Hanson, 2014; Bassetti et al., 2020). Despite the high cost of this technique, it could replace conventional species identification techniques thanks to its rapidity and accuracy. PNA-FISH uses fluorescent in situ hybridization (FISH) on specific *Candida* rRNA. It allows the detection of five *Candida* species (*C. albicans*, *C. glabrata*, *C. parapsilosis*, *C. tropicalis*, and *C. krusei*) from a positive blood culture bottle. This test does not have 100% sensitivity o, in fact if the species found is not one of the five mentioned, the test will be falsely negative.

The T2 candida panel is a molecular diagnostic test combining whole blood PCR and T2 magnetic resonance detection. This tool is independent of blood culture, providing a major advantage compared to other techniques. Almost all of the process is automated: after collecting three milliliters of whole blood, red blood cells and *Candida* cells are lysed to amplify *Candida* DNA, which is then detected by magnetic resonance. The assay identifies and results in *C. albicans* and/or *C. tropicalis* or *C. parapsilosis* or *C. glabrata*

and/or *C. krusei*; not allowing a distinction between *C. albicans* and *C. tropicalis*, or between *C. glabrata* and *C. krusei*. Its main limitations are the cost and the decrease in sensitivity if yeast cells are not intact in blood samples (Ibáñez-Martínez et al., 2017; Neely et al., 2013). This assay also should be validated in case of deep-seated candidiasis, especially when there is no candidemia (Zacharioudakis et al., 2018).

Use of clinical score to help in the diagnosis of invasive candidiasis

Clinical prediction scores have been implemented to advance the diagnostic process. They are mainly based on combination of risk factors for IFD as mentioned above. These algorithms allow early and appropriate medical intervention to lower IFD mortality. The *Candida* Score uses four risk factors for invasive candidiasis (*Candida* colonization, surgery on intensive care unit admission, sepsis, and total parenteral nutrition) (León et al., 2006). In a prospective study it has shown good negative predictive value of invasive candidiasis under certain conditions: if the score is less than three, if the patient is non-neutropenic, had been admitted to ICU for at least 7 days and has not received antifungal treatment (León et al., 2009). Due to high negative predictive values and low positive predictive values, these clinical prediction scores would be more useful to stop unnecessary antifungal treatment than to diagnose invasive candidiasis (Eggimann et al., 2011; Pfaller and Diekema, 2007).

General information on antifungal treatments

The main antifungal drugs active on *Candida* spp. and their special features are detailed in Table 1.

Oropharyngeal candidiasis (OPC)

Also called thrush, OPC is observed in infants, elderly, denture wearers, and HIV seropositive patients, of which it is one of the first and most frequent clinical manifestations. Some treatments favor the occurrence of OPC in particular antibiotic therapy, immunosuppressive treatments, and inhaled corticosteroid therapy. It results in diffuse erythematous inflammation of the oropharyngeal mucosa and of the tongue which appears stripped. Whitish deposits, which can be removed by scraping, appear secondarily. A perleche can be associated. In chronic forms, leukoplakia or mucous atrophy (black tongue) can be observed. The clinical symptoms are often mild (dry mouth, ageusia, burning sensation) but can have serious consequences in infants and malnourished patients with severe dehydration or malnutrition.

The diagnosis is essentially clinical. Identification of species and resistance screening are required during recurrences in patients who had previously been exposed to azoles. Deposit scraping samples are seeded on a specific culture medium. In non-immunocompromised patients, discreet lesions can be treated with topical treatments (AmB suspension, miconazole buccal gel). For larger lesions, oral fluconazole 7–14 days is recommended. Treatment for HIV seropositive patients is indicated in Table 2 (Lortholary et al., 2012).

Esophageal candidiasis (EC)

Rarely observed in immunocompetent patients, EC is more frequent during chemotherapy or mediastinal irradiation for malignant diseases and during AIDS. Although it may be diagnosed in the absence of OPC, EC is often due to locoregional OPC dissemination. The main symptom is dysphagia, sometimes associated with retrosternal pain. Coexistence of these symptoms and thrush should be enough to start anti-*Candida* systemic treatment and to look for immunosuppression.

The only way to confirm diagnosis is upper digestive endoscopy with targeted biopsies. It is necessary if symptoms persist under appropriate treatment. Esophageal endoscopy has two other indications:

- screening for an associated infection, in particular during AIDS (herpes simplex virus, cytomegalovirus);
- identification of the responsible strain in the event of suspected resistance to common antifungals, or of recurrence.

Endoscopic exploration reveals lesions similar to those observed in thrush with mucosal inflammation and whitish pseudo-membranes that can partially obstruct the esophageal lumen. Ulcerated lesions are scarce. The infection can spread contiguously to the stomach. Treatment indicated in Table 2 is similar for both HIV and non-HIV patients.

Vulvovaginal candidiasis

Vulvovaginal candidiasis is a very frequent infection, 75% of women having at least one episode in their life. The diagnosis is suggested in cases of intense vulvar pruritus accompanied by dyspareunia, burning sensation or dysuria, and white leukorrhea with a curdled appearance (slatted secretions). Vulvovaginal candidiasis is hormone dependent. Rare before puberty and after menopause, it can be triggered by pregnancy, antibiotic therapy, or immunosuppression. Vulvovaginitis can be treated with imidazole prolonged-release intravaginal capsules and local cleansing with alkaline soap. It is necessary to seek and treat a genital candidiasis in the partner. Recurrent candidiasis (more than four episodes per year) can be treated with cyclical fluconazole or itraconazole (Table 2).

Table 1 Principal systemic antifungals used in the treatment of adult candidiasis and their particularities.

<i>FAMILY NAME site of action</i>	<i>DCI</i>	<i>Particularities</i>	<i>Administration</i>	<i>Toxicity</i>	<i>Specific diffusion sites</i>
AZOLES inhibit synthesis of fungal membrane by inhibiting the enzyme responsible for the transformation of lanosterol into ergosterol	Fluconazole	- fungistatic on yeasts - Few drug interactions - Renal excretion - Half-life: 25 h, allowing a once-a-day dosing regimen - <i>C. glabrata</i>: decreased sensibility - <i>C. krusei</i>: resistant	PO = IV First day loading dose: twice maintenance dose Maintenance dose: • 200 mg/day for urinary candidiasis for 14 days • 200–400 mg/day for esophageal for 14–21 days • 400 mg/day for systemic candidiasis Maximum dose: 1200 mg/day	Excellent tolerance	Brain, CSF, eyes, bone, kidneys
	Voriconazole	- fungistatic on yeasts - Hepatic metabolism by cytochrome P450 (drug interactions) - half-life: 6–9 h - Plasma level monitoring recommended: therapeutic value between 1 and 4 mg/L; if residual plasma concentration >5 mg/L, risk of hepatic and neurologic toxicity	IV, PO (empty stomach) First day loading dose IV: 6 mg/kg/12 h PO: 200–400 mg/kg/12 h Maintenance dose: IV 4 mg/kg/12 h PO 100–200 mg/kg/12 h	Renal toxicity with IV administration, reversible visual disturbances Photosensibility; risk of epidermoid carcinoma during prolonged treatments Cholestatic and cytolytic hepatitis Few side effects (neutropenia, neurosensory disturbances, QT prolongation, cholestatic hepatitis)	CSF, eyes
	Posaconazole	- fungistatic on yeasts - Hepatic metabolism by cytochrome P450 (drug interactions) Plasma level monitoring. . . - Indicated in oropharyngeal candidiasis (OPC) including OPC refractory (rOPC) to itraconazole and/or fluconazole - prophylaxis of invasive candida infections in patients who are at high risk (HSCT recipients with GVHD or those with hematologic malignancies with prolonged neutropenia from chemotherapy) - Not indicated in esophageal candidiasis and candidemia	- IV - 400 mg × 2/day during fatty meals, after a loading dose divided in 4 doses/day (200 mg × 4) during 48 h - gastro-resistant tablets: loading dose day 1 300 mg × 2/then 300 mg/day		
	Itraconazole	- erratic absorption (capsules to be taken during meals, oral solution on empty stomach) - Hepatic metabolism by cytochrome P450 (drug interactions) Plasma level monitoring. . .	- Loading dose IV 200 mg/12 h or PO 400–600 mg during 48 h - maintenance dose: IV 200 mg/day PO 400 mg/day	- severe liver disease - worsening of congestive cardiomyopathy	- poor dissemination in LCS
	Isavuconazole	- lower interactions than other azoles but be careful with rifampicin and tyrosine-kinase inhibitors - indicated for invasive aspergillosis as an alternative to voriconazole - indicated mucormycosis in case of intolerance to AmB	- same dosage if intravenous or oral form - loading dose 200 mg/8 h on D1 and D2 - maintenance dose: 200 mg/day	- some headache, drowsiness - lower liver and skin toxicity than voriconazole - caution in patients with hepatic failure: risk of overdose	- good dissemination in cerebral parenchyma but poor in CSF

POLYENES alter membrane permeability by binding to membrane ergosterol	AmB	- weak oral absorption (>5%)	- IV: 0.7–1 mg/kg	- renal insufficiency	Brain, kidneys, eyes, bone
	deoxycholate	- Half-life: 24–48 h	- Duration: ≥ 4 h	- Anemia	
	AmB liposomal ^a	- not dialyzable	IV: 3–5 mg/kg	- Electrolyte disturbances (hypokalemia and hypomagnesemia)	
		- ineffective on <i>C. lusitanae</i>		- Test dose: 1 mg in 20 min	
		- Renal excretion	- Duration: 1–2 h but more if intolerance		
		- good tissue diffusion			
ECHINOCANDINS alteration of fungal wall by inhibiting beta 1-3-glucan synthase	Caspofungin	- Fungicidal on yeasts	over 1 h	for AmB liposomal: better renal tolerance	Renal parenchyma, ocular involvement
		- IV only	First day loading dose	Common:	
		- Hepatic elimination	70 mg	disturbance of liver function	
		- Risk of resistance in <i>C. guilliermondii</i> and <i>C. parapsilosis</i>	Maintenance dose 50 mg/day	(augmentation of AST and ALT, -GT, alkaline phosphatase)	
		- not dialyzable	<80kg		
			70mg/day ≥ 80 kg		
			- Dose adjustment for hepatic insufficiency		
			- absence of adjustment if renal insufficiency		
	Micafungine		No loading dose		
			max 150 mg/j		
	Anidulafungine		Loading dose 200 mg		
			Maintenance dose		
			100 mg/day		
PYRIMIDINE inhibits nucleus DNA and RNA synthesis	Flucytosine	- Inactive on <i>C. krusei</i>	PO	- Hematological	Brain, CSF, kidney, eyes, bone
		- High risk of secondary resistance: always prescribed in association with other drugs	100–200mg/kg/day	- Hepatic (cytolysis)	
		Plasma level monitoring. . .		- Gastrointestinal	
		- Renal excretion		- (ulcerative membranous enterocolitis)	

AmB: amphotericine B; IV: intravenous; PO: per os.

^aThe lipid forms of amB are generally indicated if the patient has pre-existing renal failure or has developed one under treatment. (Creatinine >220 μ mol or clearance less than 25 mL/min), except for special indications.

Table 2 Treatment of oro-pharyngeal candidiasis (OPC), esophageal candidiasis (EC) and vulvo-vaginal candidiasis in HIV patients.

Primary prophylaxis in mucosal involvement	Treatment
Treatment of first episodes of OPC (with or without identification of an azole susceptible strain)	• Introduction or monitoring of ARV therapy • Fluconazole (100 mg/day) • or Miconazole gingival muco-adhesive pill (50 mg/day) • or Itraconazole oral solution after fasting (200 mg/day) • Response within 72 h • Treatment duration 7 days, to be renewed 7 days in case of failure • Therapeutic response in 80% of cases
Treatment of EC ^a	• Initiation of treatment without prior endoscopy • Endoscopy not necessary if patients have esophageal symptoms and lesions of oropharyngeal candidiasis • Fluconazole per os (200 mg/day for 14–21 days) possibly increased to 400 mg/day in the case of clinical failure • or Itraconazole oral solution after fasting (200 mg/day, 1 or 2 doses)
Treatment of resistant OPC/EC Symptoms persisting after 2 weeks of Fluconazole treatment with a dose higher than 200 mg/day	• A sample must be taken to identify the responsible species and test its fluconazole susceptibility in vitro • Itraconazole oral solution after fasting (200–600 mg/day during 2 weeks; in the absence of clinical improvement, treatment can be continued for 2 weeks) • Or Posaconazole suspension (100 mg b.i.d) to be administered with a fatty food • Or Echinocandin • Or Voriconazole
Treatment of vulvo-vaginal candidiasis ^a	• Topical agents (azole vaginal capsule: econazole LP 150 mg 1 capsule at night) • Or short course of azole per os: single 150 mg oral dose of fluconazole • Disease recurrence^b: 10–14 days of induction therapy with a topical agent, then fluconazole per os 150 mg/week for 6 months

^aDoes not differ whether the patient is immunosuppressed or not.^bMore than 4 episodes per year.

Mucosal candidiasis in HIV-seropositive patients

OPC or EC are very common and considered to be markers of immunosuppression. Prior to the arrival of highly active anti-retroviral treatments (HAART), about 90% of HIV-positive patients had OPC. OPC and EC are favored by CD4 T cells less than 200/mm³. *C. albicans* is the most common species involved. Acquired resistance to fluconazole is observed after exposure to large or frequent doses of fluconazole or by direct transmission of a resistant strain; 93% of patients still remain susceptible to fluconazole despite repeated use of azoles. In parallel with *C. albicans* resistance, new less-susceptible-to-fluconazole species are found on the oral mucosa and vaginal mucosa (*C. krusei* and *C. glabrata*). *C. glabrata* is responsible for frequent relapses, especially in patients with advanced immunosuppression.

Occurrence of genital candidiasis is not linked to the severity of immune deficiency in HIV patients. Management is therefore the same as in the general population.

Although some studies have shown the benefit of preventive OPC treatment with fluconazole, primary prophylaxis is not recommended in Europe. Risks of drug interactions with HAART, development of resistance, cost of long-term courses of therapy and potential toxicity of the drugs are not in favor of primary prophylaxis (Lortholary et al., 2012).

Secondary prophylaxis is recommended only when relapses are frequent or severe after initiating optimal HAART. Maintaining treatments after immune reconstitution (i.e., CD4 count $\geq 200/\text{mm}^3$) is not recommended (Blanc et al., 2018; Lortholary et al., 2012).

Skin and nail candidiasis

Intertrigo due to *Candida* spp. appears as yellowish white deposits on erythematous skin. There may also be a “crumbled” aspect of the lesions at the periphery (small erythematous papules). The diagnosis is essentially clinical but samples for mycological confirmation can be made. Treatment involves the prevention of risk factors such as maceration and topical imidazole treatments.

Onychia or perionyxis begins with inflammation around the nail and with moderate pain, followed by a transparent exudate. The nail is then invaded through the lateral edge by a yellow spot that reaches the free edge. The diagnosis is made by direct examination and culture of nail samples. After cutting the sick nail, the treatment consists in application of an imidazole cream on the perionyxis and the lateral furrows. Treatment with film-forming solution can speed up healing. Local treatments are effective only on mild lesions of a single finger in immunocompetent patients. In other cases, systemic treatment is associated with local treatment after *Candida* identification.

Peritonitis

Peritonitis frequency is increasing. It can complicate peritoneal dialysis, digestive surgery, intestinal perforation or advanced cirrhosis. Dissemination is most often hematogenous, except during peritoneal dialysis. It is associated with significant morbidity and mortality between 20% and 30%. Isolation of *Candida* spp. from a postoperative peritoneal drain does not necessarily require treatment but strengthened clinical and microbiological monitoring is desirable.

The diagnosis requires direct examination and culture of the peritoneal fluid. There are four predictive factors of mortality due to polymicrobial peritonitis with *Candida* isolation in peritoneal fluid in critically ill patients: APACHE II (Acute Physiology and Chronic Health Evaluation II) score on admission of at least 17, respiratory failure on admission, upper gastrointestinal tract site of peritonitis, and results of direct examination of peritoneal fluid that were positive for *Candida* spp. (Dupont et al., 2002).

For treatment of *Candida* peritonitis, several learned societies have attempted to give clear guidelines for treatment. The presence of live yeast in peritoneal fluid is associated with excess mortality (Montravers et al., 2015). Clinical features suggestive of yeast infection are hemodynamic failure, upper gastrointestinal perforation, female gender, and antibiotic therapy during the previous 48 h. When 3 of these 4 criteria are present, the probability of isolating *Candida* in peritoneal fluid is 71%: in this case empirical antifungal therapy should be introduced. In healthcare-associated intra-abdominal infections, an echinocandin treatment should be preferred if yeasts are observed at direct examination and if peritoneal fluid culture is positive. Introducing antifungal therapy is not necessary in community peritonitis in the absence of severity signs except in immunocompromised patients, transplant recipients or patients with an inflammatory disease (Montravers et al., 2015).

IDSA guidelines suggest considering empiric antifungal therapy for patients with clinical evidence of intra-abdominal infection and significant risk factors for candidiasis, including recent abdominal surgery, anastomotic leaks, or necrotizing pancreatitis, who are doing poorly despite treatment for bacterial infections. The recommended treatment is echinocandin (Caspofungin: loading dose of 70 mg, then 50 mg daily; Micafungin: 100 mg daily; Anidulafungin: loading dose of 200 mg, then 100 mg daily) (Pappas et al., 2016; Sartelli et al., 2017).

Candiduria

Candiduria is defined by isolation in the urine of *Candida* spp. colonies whatever the threshold (Pappas et al., 2016). Candiduria may reflect candidemia or an isolated infection of the urinary system. Most of the time, it is a simple colonization of the bladder mucosa. It can occur in patients with a urinary catheter, in diabetics, at extreme ages (premature, elderly), during the extension of a vaginal infection and when using broad-spectrum antibiotics. The other known risk factors are urinary tree abnormalities and abdominal surgeries. Candiduria is also more frequent in intensive care units (Achkar and Fries, 2010).

The infection can be asymptomatic or revealed by classic signs of cystitis. Sometimes it spread to kidneys with the formation of abscesses or obstruction of the urinary tract with fungus ball. The risk of ascending kidney damage is more frequent in the event of obstacle, intra-ureteral device or in diabetics. Nevertheless, hematogenous spread still remains the cause number one of *Candida* kidney abscesses.

Clinical examination to search for signs of disseminated infection is mandatory once candiduria is detected (Pappas et al., 2016). In women, prescription of antifungal vaginal capsules or a bladder catheter for urine sampling may be necessary to confirm candiduria and avoid false positives due to vulvovaginal candidiasis. Leukocyturia or positivity of other mycological samples can help to differentiate colonization and true infection. There is no quantitative threshold in the urine to define the infection (Table 3).

Table 3 ESCMID and IDSA recommendations for the treatment of *Candida* spp. urinary tract infections.

Patient	Treatment ^a
Asymptomatic	None, except for patients with high risk of dissemination (neutropenia, infants born hypotrophic <1500 g, planned urologic intervention) - If urologic intervention: Oral fluconazole 400 mg/day or AmB deoxycolate 0.3–0.6 mg/kg/day for several days before and after the procedure - If neutropenic patients or very-low-birth-weight infants: candidemia treatment (echinocandin at initial therapy) Removal indwelling bladder catheters
Pyelonephritis	Fluconazole 200–400 mg/day for 2 weeks if fluconazole susceptible strain If fluconazole-resistant strain <i>C. glabrata</i> : AmB-d 0.3–0.6 mg/kg/day or oral flucytosine 25 mg/kg 4 times per day for 2 weeks ^b <i>C. krusei</i> : AmB-d 0.3–0.6 mg/kg/day Elimination of urinary tract obstruction if present
Cystitis	Fluconazole 200 mg/day for 2 weeks if fluconazole susceptible strain If fluconazole-resistant strain (<i>C. glabrata</i> or <i>C. krusei</i>) AmB-d 0.3–0.6 mg/kg/day for 1–7 days Or oral flucytosine ^b 25 mg/kg × 4/day during 7–10 days
Fungus ball	- Irrigation through nephrostomy tubes, if present, with AmB-d, 25–50 mg in 200–500 mL sterile water ^c

AmB-d = amphotericin B deoxycolate.

^aMaintenance doses are indicated in the table, loading dose of azoles should be administered the first day or during the first 2–3 days depending on azole chosen.

^bThe excellent urinary diffusion of flucytosine allows it to be used as monotherapy in this case.

^cLipid forms of AmB have low urinary diffusion at standard doses, but may have higher efficacy at higher doses.

Systemic candidiasis

The indications and treatments are detailed in Table 4.

Table 4 ESCMID and IDSA recommendations for the treatment of systemic candidiasis depending on the affected organ.

TYPE OF INFECTION		TREATMENT ^a
Candidemia without organ involvement		• 1 blood culture per day until obtaining negative results • 14 days of treatment after the end of candidemia and resolution of symptoms attributable to candidemia • oral relay possible with fluconazole (loading dose 800 mg (12 mg/kg) then 400 mg (6 mg/kg) per day) as soon as patient is clinically stable, the species is susceptible, and repeated blood cultures are negative • testing for azole susceptibility is recommended for all blood stream infection and other clinically relevant <i>Candida</i> isolates
Ocular involvement	Central catheter can be removed	Removal of catheter
	Central catheter cannot be removed	Use an antibiofilm antifungal drug: Echinocandin, liposomal AmB or lipid complex AmB
	Chorioretinitis without vitritis with isolated resistant strain to fluconazole/voriconazole	IV L-AmB 3–5 mg/kg daily ± flucytosine oral 25 mg/kg 4 times daily
	Chorioretinitis without vitritis with isolated susceptible strain	- Fluconazole, loading dose, 800 mg then 400–800 mg once a day OR Voriconazole loading dose of 6 mg/kg IV twice daily for 2 doses, followed by 4 mg/kg IV or oral twice daily - Duration should be at least 4–6 weeks, depending on resolution of the lesions - Same IV treatment plus intravitreal injection of AmB-d 5–10 µg or voriconazole 100 µg - Vitrectomy should be considered to decrease fungal burden and to remove fungal abscess
	Chorioretinitis with vitritis	
Meningitis		- L-AmB 5 mg/kg daily ± flucytosine 25 mg/kg 4 times daily followed by fluconazole 6–12 mg/kg daily after initial response to treatment - therapy should be continue until all signs and symptoms, and CSF and radiological abnormalities have resolved. Generally, L-AmB ± flucytosine for 10 weeks followed by fluconazole for 5 weeks
Endocarditis	Native valve	- Initial therapy: AmB lipid formulation 3–5 mg/kg daily ± flucytosine 25 mg/kg 4 times daily at initial therapy OR high dose echinocandin (casprofungin 150 mg daily, micafungin 150 mg daily or anidulafungin 200 mg daily) - Followed by fluconazole (6–12 mg/kg daily) for patients who have susceptible <i>Candida</i> isolates, were clinically stable, and have negative blood cultures - Surgery within the week is recommended - duration of 6 weeks after surgery
	Valvular prosthesis	- Urgent surgery (in the following days) and same antifungal treatment as native valve - chronic suppressive antifungal therapy with fluconazole (6–12 mg/kg daily) to prevent recurrence
	Valvular prosthesis with contraindication for excision	- long term suppression with fluconazole (6–12 mg/kg) daily if the isolate is susceptible
Osteomyelitis (including vertebral)		- Surgical debridement in selected cases - Fluconazole 400 mg (6 mg/kg) daily for 6–12 months OR an echinocandin (casprofungin 50–70 mg daily, micafungin 100 mg daily, anidulafungin 100 mg daily) for at least 2 weeks followed by fluconazole 400 mg per day for 6–12 months - Another less attractive alternative due to renal toxicity: AmB lipid formulation 3–5 mg/kg for at least 2 weeks followed by fluconazole 400 mg (6 mg/kg) for 6–12 months
Arthritis		- Surgical drainage in all cases - Fluconazole 400 mg (6 mg/kg) daily for 6 weeks OR an echinocandin (casprofungin 50–70 mg daily, micafungin 100 mg daily, anidulafungin 100 mg daily) for 2 weeks followed by fluconazole 400 mg per day for at least 4 weeks - Another less attractive alternative: lipid formulation AmB 3–5 mg/kg for 2 weeks, followed by fluconazole 400 mg for ≥ 4 weeks
Joint prosthesis infection		Prosthesis removal If prosthesis left in place: chronic suppression by fluconazole 400 mg/day

AmB, amphotericin B; Amb-d, amphotericin B deoxycholate; L-AmB, liposomal amphotericin B.

^aMaintenance doses are indicated in the table, loading dose of azoles should be administered the first day or during the first 2–3 days depending on azole chosen.

Candidemia

Candidemia is defined by one or more blood cultures positive for *Candida* spp. without clinical signs of dissemination. To confirm the absence of secondary localizations, retinal examination and transthoracic echocardiography should systematically be performed. A study has shown that transthoracic echocardiography alone can miss one third of clinically unsuspected endocarditis, suggesting systematic transesophageal echocardiography (Fernández-Cruz et al., 2015). Another study found a much lower incidence of endocarditis, suggesting that transthoracic ultrasound should be done only if risk factors such as prosthetic heart valves, injecting drug users, prolonged candidemia, new onset heart failure or embolic events are present (Cleveland et al., 2015; Cornely et al., 2012).

If the patient is immunocompromised, the risk of systemic infection is very high and treatment should be started immediately. Disseminated candidiasis should be carefully searched, removal of all catheters should be discussed, and blood cultures repeated daily until negative.

It is now widely accepted in the general population as well as in the hematological population that the withdrawal of a central venous catheter and early establishment of an adequate antifungal treatment are two factors that could reduce mortality (Garnacho-Montero et al., 2013). It is recommended to use a treatment with anti-biofilm activity (echinocandin or a lipid formulation of amphotericin B) if the central catheter cannot be removed (Seidler et al., 2010; Shuford et al., 2006).

Disseminated candidiasis

Acute disseminated candidiasis

Acute disseminated *Candida* infections are generally associated with sepsis or septic shock. Symptoms are unspecific and can lead in several days to shock with multiple organ failure, especially in neutropenic patients. In that case, mortality rate exceeds 50%. Blood cultures being negative in more than half of the cases, the diagnosis must therefore be suggested, and preemptive antifungal treatment should always be considered in neutropenic patients with persistent fever under broad spectrum antibiotic therapy. Oropharyngeal and digestive colonization with *Candida* spp. is an additional argument to start antifungal treatment. Biopsies (oral, ocular or osteoarticular candidiasis) can provide diagnosis of certainty by allowing yeast isolation.

Septic metastases are common. Secondary locations can be:

1. ocular, especially endophthalmitis, present in 28% of cases. A dilated eye exam reveals chorioretinitis with cottony nodules and hyalite and it can also reveal an extension to the vitreous body.
2. cutaneous: erythematous nodules and macules, sometimes necrotic (ecthyma gangrenosum).
3. renal: the most frequent after cutaneous and ocular localizations;
4. osteoarticular: mainly in drug addicts. Osteomyelitis and vertebral osteomyelitis often require surgical management associated with antifungal treatment (48%) (Gamaletsou et al., 2012);
5. central neurological: brain abscess, meningitis;
6. myocardial: often discovered at autopsy, can result in arrhythmia or conduction disturbances, or even heart failure.

The lungs and adrenal glands are more rarely affected.

Endocarditis

Candida endocarditis is rare with increasing incidence around 2–4% due to the use of endovascular prostheses (Antinori et al., 2014). The two main risk factors are prosthetic valves and short-term indwelling catheters. Patients with prosthetic valves may be at risk of postoperative transient candidemia. *Candida* colonizes the valve prosthesis thanks to biofilm production, which reduces susceptibility to antifungal agents (Falcone et al., 2009; Nasser et al., 1997). Symptoms are similar to those of bacterial endocarditis, while vegetations are often larger with high embolic risk requiring surgical management. Even with adequate care, mortality is high (around 56%). The two major causes of death are cardiac failure and uncontrolled sepsis (Rivoisy et al., 2018).

Osteomyelitis and arthritis

Being rare, these infections are sparsely studied, and little is known about their pathophysiological mechanisms. For *Candida* osteomyelitis, more than half of the patients are immunocompetent with an average age around 30 years (Gamaletsou et al., 2012). Hematogenous dissemination seems to be the first cause of osteoarticular involvement (67%) followed by direct inoculation (24%) and infection contiguous (9%), associated candidemia being found in less than 20% of the cases. The most frequent localizations are vertebrae (>50%), femur, ribs and sternum with discrepancies according to age: adults have predominant vertebral involvements whereas children have long bone involvements (Gamaletsou et al., 2012; Slenker et al., 2012).

Over 90% of osteoarticular infections are due to a single species of *Candida*. The most commonly found species is *C. albicans* (>50%), followed by *C. tropicalis* (16%), *C. glabrata* (8%), and *C. parapsilosis* (7%), reflecting the overall epidemiology of *Candida* spp. (Gamaletsou et al., 2012).

Few patients remain asymptomatic. The most commonly reported symptoms are localizing pain, tenderness and/or edema. Fever has been reported in less than a third of patients. Infection may evolve with few signs delaying the diagnosis for several weeks to several months.

Regarding treatment management, no antifungal drug has been proven superior. Based on expert experience (B-III, level of evidence), the 2016 IDSA guidelines for *Candida* osteomyelitis recommend fluconazole 400 mg (6 mg/kg) daily for 6–12 months or

an echinocandin (caspofungin 50–70 mg daily, micafungin 100 mg daily, or anidulafungin 100 mg daily) for at least 2 weeks followed by fluconazole, 400 mg (6 mg/kg) daily for 6–12 months. (Cornely et al., 2012; Pappas et al., 2016) Use of Lipid formulation AmB, 3–5 mg/kg daily, instead of echinocandin is less attractive.

Surgical management seems beneficial especially in cases of functional impairment such as neurological deficit, or vertical instability, or when the antifungal treatment alone seems ineffective.

A literature review evaluated 112 cases of *Candida* arthritis between 1967 and 2014 (Gamaletsou et al., 2016). Surprisingly, more than half of the patients (65%) were non-immunocompromised. *Candida* septic arthritis most commonly occurred post-surgically (35%). Almost two-thirds of the patients (63%) had initial candidemia or another form of candidiasis (ocular, central nervous system involvement or an infected central venous catheter).

The clinical manifestations most often found are pain, tenderness, edema; and the most affected joints are knees, hips, and shoulders. The two *Candida* species most often found are *C. albicans* and *C. tropicalis*. The goal of early and appropriate treatment is to limit bone destruction and joint effusion. The latest recommendations from IDSA 2016 recommend using fluconazole, 400 mg (6 mg/kg) daily, for 6 weeks or echinocandin (caspofungin 50–70 mg daily, micafungin 100 mg daily or anidulafungin 100 mg daily) for 2 weeks followed by fluconazole, 400 mg (6 mg/kg) daily, for at least 4 weeks. Surgical drainage is indicated in all cases of septic arthritis (Pappas et al., 2016).

Chronic disseminated candidiasis

Chronic disseminated candidiasis (CDC), improperly called hepatosplenic candidiasis, affects liver and/or spleen, and also lungs, kidneys, and CNS. It occurs exclusively after a period of deep and prolonged neutropenia lasting more than 10 days. The incidence of CDC in acute leukemia is probably around 3–5%. The most common symptom is isolated fever that does not respond to broad spectrum antibiotic therapy while the patient is recovering from neutropenia. Other signs may be right upper quadrant pain, hepatomegaly, splenomegaly, or dry cough. Liver enzymes are generally disturbed with cholestasis; inflammation markers are high. Blood cultures are positive in approximately 15–20% of patients. (Candon et al., 2020) Ultrasound or CT guided liver biopsies sometimes reveal yeast and granuloma in histopathology. They generally remain sterile in culture. They allow differential diagnosis such as mycobacteriosis. Most of the CDCs whose agents have been identified are due to *C. albicans*. Serum biomarkers such as BDG, mannan antigens/anti-mannan antibodies may be helpful in CDC diagnosis. Currently, MRI is considered to be the most sensitive exam to detect less than one-centimeter abscesses in liver and/or spleen before CT and ultrasound. It takes several weeks/months for lesions to disappear from conventional imaging. 18F-fluorodeoxyglucose positron emission tomography-computed tomography could be used for initial diagnosis and monitoring of patients.

A recent study has demonstrated that CDC is associated with IRIS, mainly due to the presence of a significant biological inflammatory syndrome, the very common absence of associated candidemia, the presence of epithelioid granulomas in liver tissue, and a good clinical-biological response to high doses of corticosteroids. *Candida* specific T cells producing interferon-gamma (IFN- γ) at a high rate have been shown to be useful in CDC diagnosis (Candon et al., 2020; Sallah et al., 1999).

The IDSA and the ESCMID recommend a protracted course of antifungal treatment (Table 4). (Pappas et al., 2016) Corticosteroids may be used to improve symptoms but not biological and radiological signs.

Candidiasis in organ transplantation

One-year incidence for invasive candidiasis in the US cohort named Transplant - Associated Surveillance Network (TRANSNET) was 1.95% (Pappas et al., 2010). Invasive candidiasis represents 53% of IFD (Pappas et al., 2010). In this cohort, one-year incidence of IFD was highest in small bowel transplant recipients, whereas prevalence of *Candida* infection was highest in liver transplant recipients, followed by kidney and pancreas transplant recipients. All-cause mortality at 90 days was 26.5% for all species in solid organ transplant recipients (SOT) (Andes et al., 2016).

The diagnostic methods and treatments for candidemia and invasive candidiasis in SOT follow the 2016 IDSA recommendations. However, special features should be noted, notably in lung transplant recipients, where tracheobronchitis caused by *Candida* spp. must be treated.

In transplant recipients, antifungal prophylaxis is guided according to at-risk patients (Table 5) (Giannella et al., 2018). This approach seeks to reduce the number of adverse events and drug-drug interactions, and to limit costs. During liver transplantation, prophylaxis in at-risk patients only has been shown to be an effective strategy to reduce the risk of IFD, thereby reducing exposure to azoles (Lavezzo et al., 2014; Pappas et al., 2006). It is not recommended to introduce antifungal prophylaxis either in heart transplant recipients or in renal transplant recipients. In pancreatic transplantation, prophylaxis is controversial. According to the American Society of Transplantation Infectious Disease Community of Practice, it is recommended to use an antifungal prophylaxis only if at least one risk factor is present (Table 5).

In hematopoietic stem cell transplant (HSCT) patients, *Candida* prophylaxis is recommended during the pre-engraftment period with Fluconazole (400 mg/day) for centers with a low incidence of mold infections (<5%). Centers with a higher incidence of mold infections should prefer anti-mold prophylaxis. During the post-engraftment period, anti-mold prophylaxis is advised if GVH disease occurs. The fifth European conference on leukemic infections (ECIL-5) recommended using echinocandin as first-line curative treatment in the event of candidemia/invasive candidiasis followed by a step-down approach in clinically stable patients upon receipt of species identification and antifungal susceptibility testing results (Tissot et al., 2017). The three echinocandins (caspofungin, micafungin and anidulafungin) now have the same grade (A II) recommendation in hematological patients (Krishnan-Natesan et al., 2010).

Table 5 Candidiasis primary chemoprophylaxis in transplant recipients.

Indication	Primary prophylaxis	Doses	Duration post-transplant
High risk in liver transplantation ^a	Fluconazole	100–400 mg/day	At least 14–28 day
Pancreatic ^b	<i>Alternative:</i> Echinocandin		At least 14–28 day
	Fluconazole	400 mg/day	≥ 4 weeks
	OR		
	Liposomal AmB or echinocandin ^c		
Small bowel ^d	Fluconazole	400 mg/day	≥ 4 weeks (until the anastomosis has completely healed and rejection is not present)
	OR		
	Liposomal AmB or echinocandin ^c		
Hematopoietic stem cell	Fluconazole in centers with incidence <5% of mold infections	400 mg/day	During pre-engraftment until neutrophil recovery

^aDefined by re-transplantation, re-operation, renal failure requiring hemodialysis, transfusion of ≥ 40 units of cellular blood products, choledochojejunostomy, and Candida colonization in the perioperative period. MELD (Model for End-stage Liver Disease) score ≥ 30, biliary leaks, and living liver transplantation.

^bRisk factors: enteric drainage, vascular thrombosis, and post-perfusion pancreatitis.

^cIn centers with high prevalence of non-albicans Candida. Echinocandin dosage (Caspofungin: 70 mg then 50 mg/day or Micafungin 100–150 mg/day) Liposomal AmB dosage: 3–5 mg/kg/day.

^dRisk factors: Graft rejection or dysfunction, enhanced immunosuppression, anastomotic disruption, abdominal re-operation, or multivisceral transplantation.

Conclusion

Candidiasis remains a severe disease with a poor prognosis despite therapeutic and diagnostic advances. Technology advances will allow faster and more targeted diagnosis for better treatment. This step forward is crucial due to emergence of low susceptibility species with regard to current antifungal therapies. Judicious use of antifungal drugs and better knowledge of risk factors may limit the expansion of these threatening species.

Aspergillus and aspergillosis

Aspergillus species are omnipresent saprophytes that can thrive on different organic matter owing to their capacity to adapt with a range of environmental conditions (Cray et al., 2013) (Fig. 1). Asexual spores (conidia) are formed by *Aspergillus* species as propagates that are airborne and highly tolerant to environmental stress, while some species are also known to have sexual life-cycle forming ascospores (Stevenson et al., 2015; Wyatt et al., 2015). Being an opportunistic pathogen, depending on the immunosuppression host factor and underlying lung disease, *Aspergillus* species can cause a spectrum of diseases of the upper and lower respiratory tract from benign maxillary sinus aspergilloma to severe invasive pulmonary aspergillosis: (i) individuals severely immunocompromised will develop invasive pulmonary and/or sinus aspergillosis that rarely disseminates, but can involve the central nervous system (CNS), leading to CNS aspergillosis, the most severe form of extrapulmonary aspergillosis, (ii) those with underlying lung disease with structural modification and/or chronic inflammation may develop chronic pulmonary aspergillosis, and (iii) those with hypersensitivity and allergic background are prone to develop allergic bronchopulmonary aspergillosis (ABPA) or severe asthma with fungal sensitization. Regardless of the forms of aspergillosis, the most prevalent *Aspergillus* species is *A. fumigatus* (responsible for >90% infection), followed by *A. flavus*, *A. niger*, and less commonly, *A. terreus*, *A. nidulans* and *A. versicolor* [reviewed in (Paulussen et al., 2017)].

The spectrum of aspergillosis

Invasive pulmonary aspergillosis (IPA) is a well-known complication in immunocompromised individuals, specifically in neutropenic patients with acute leukemia, stem cell and solid organ transplant recipients as well as patient receiving high dose

*Contributed equally.

Fig. 1 *Aspergillus* species inhabit different organic matter. Asexual spores (conidia) produced by them are dispersed through air-current, which allow them to exploit new environment wherein they continue with saprophytic life cycle, or access to the human lungs through breathing in whom they may be eliminated by the immune system, or lead to allergy or infectious diseases.

corticosteroids (Donnelly et al., 2019). Chronic lymphoproliferative diseases has emerged as a new high-risk group (Lortholary et al., 2011), especially when patients were treated with ibrutinib (Ghez et al., 2018). It may also develop in critically ill patients without classical risk factors, most likely when the patient enters a stage of protracted immunosuppression due to various immune dysfunctions (Monneret et al., 2011). This includes patients with influenza (Schauwvlieghe et al., 2018; Shah et al., 2018; van de Veerdonk et al., 2017) and more recently, COVID-19 (Alanio et al., 2020; Bartoletti et al., 2020; Rutsaert et al., 2020; van Arkel et al., 2020). IPA has also been described in patients with severe chronic obstructive broncho-pulmonary aspergillosis (COPD) likely due to several predisposing factors including prolonged use of corticosteroid therapy, structural change in the lung architecture, broad spectrum antibiotic treatment and comorbid illnesses (Lionakis and Kontoyiannis, 2003). Global incidence of IPA has recently been updated to >300,000 cases and is likely underdiagnosed (Bongomin et al., 2017). Associated mortality remains high ranging from 30-80% (Table 1) (Bongomin et al., 2017). Environmental exposure affects incidence of the disease and nosocomial clusters have been previously reported, often linked to hospital construction and *Chronic pulmonary aspergillosis* (CPA) is a problematic pulmonary disease that complicate many other respiratory disorders and affect over 3,000,000 patients worldwide (Bongomin et al., 2017). Prior tuberculosis may be the most common underlying condition for CPA but COPD, sarcoidosis, ABPA, atypical mycobacteria lung disease are also responsible for structural lung changes and mucociliary impairment responsible for the development of CPA. The term CPA includes various entities: aspergilloma (also called fungus-ball), *Aspergillus* nodule, chronic cavitary pulmonary aspergillosis (CCPA) and chronic fibrosing pulmonary aspergillosis (CFPA), which affect non-immunocompromised patients (Denning et al., 2016). The most common form is CCPA, which may progress to CFPA if untreated. Despite milder symptoms than IPA, patients are at high risk of disease progression and hemoptysis, and mortality rate of CPA is 80% within 5 years if untreated (Kosmidis and Denning, 2015). Subacute invasive pulmonary aspergillosis affect patients with mild immune disorder including long term corticosteroid use, diabetes, malnutrition, alcohol abuse, and is a more rapidly progressive infection (Denning et al., 2016).

Allergic bronchopulmonary aspergillosis (ABPA) is a progressive allergic lung disease due to sensitization to *Aspergillus* antigens and commonly complicating asthma or cystic fibrosis. Both condition affect mucociliary clearance of fungal elements leading to fungal growth, mucosal colonization and higher exposure to fungal antigens and persisting airway inflammatory response (Tracy et al., 2016). ABPA may lead to severe lung damage, respiratory failure and increased premature mortality. Prevalence rate in asthma patient is 2.5% translating to over 4.8 million cases of ABPA in adults worldwide (Bongomin et al., 2017). Severe asthma with fungal sensitization (SAFS) describes patient with evidence of sensitization to aspergillus among other fungi but who do not meet ABPA diagnostic criteria. It is estimated that 3% of asthmatic adult will develop SAFS leading to increased severity and more frequent exacerbation (Denning et al., 2006).

Table 1 Clinical, radiological and microbiological characteristics of pulmonary aspergillosis.

	<i>Invasive pulmonary aspergillosis</i>	<i>Chronic pulmonary aspergillosis</i>	<i>Allergic bronchopulmonary aspergillosis</i>
Host factors	Neutropenia <500 cells/mm ³ HSCT Chronic lymphoproliferation Ibrutinib SOT CGD (hereditary neutrophil dysfunction) Critically ill Severe COPD	Tuberculosis COPD ABPA Sarcoidosis Bronchiectasis NTM infection Treated lung cancer	Asthma Cystic fibrosis
Incidence	>300,000 cases worldwide	>3,000,000 cases worldwide	>4,800,000 cases worldwide
Clinical features	Cough Sputum production Dyspnea Fever Thoracic pain Hemoptysis	Aspergilloma: asymptomatic CCPA: Cough ++ Fatigue, weight loss, night sweats, shortness of breath, fever, hemoptysis	Recurrent pulmonary exacerbations: cough, wheeze, shortness of breath +/- systemic features (fever, anorexia)
Radiological features on computed tomography scanning	Neutropenic Nodules with halo sign Angio-invasive aspergillosis Non-neutropenic Bronchiolitis Airway-invasive aspergillosis +/- CNS dissemination Non-specific in critically ill and COPD patients	Underlying lung disease features + Aspergilloma: intracavitary mass partially surrounded by a crescent of air ("air crescent" sign) CCPA: areas of consolidation associated with multiple expanding usually thick-walled cavities CFPA: severe fibrotic destruction of at least two lobes of lung complicating CCPA Aspergillus nodules: nodules <3 cm	Central bronchiectasis (upper lobe predominance) Bronchial wall thickening Hyper-attenuating mucoid impaction (pathognomonic ++, 20% of cases)
Microbiological criteria	Direct examination/culture from sputum, BAL or aspirate Galactomannan (serum, BAL or CSF) Aspergillus PCR (serum, BAL)	Direct examination/culture Aspergillus IgG antibodies Aspergillus precipitins	Aspergillus IgE antibodies Total IgE > 1000 IU/mL Aspergillus precipitins or IgG antibodies
Diagnostic algorithms and classification	1. EORTC/MSG if immunocompromised (Donnelly et al., 2019) 2. AspiCU if patient in ICU ^a (Blot et al., 2012) 3. Treatment guidelines	ESCMID/ECMM/ERS guidelines (Ullmann et al., 2018) IDSA guidelines (Patterson et al., 2016) ECIL guidelines (Tissot et al., 2017)	ESCMID/ECCM/ERS rational and clinical guidelines (Denning et al., 2016)	No consensual guidelines. Regimen proposed by ISHAM working group (Agarwal et al., 2013)
First line therapy	Voriconazole 2 × 6 mg/kg IV (oral 400 mg twice daily) on day 1, then 2–4 mg/kg IV (200–300 mg twice daily) or Isavuconazole 200 mg IV thrice daily on day 1–2 then 200 mg daily	Aspergilloma: observation or surgical resection if symptomatic CCPA: Itraconazole 200 mg twice daily	Oral corticosteroids (0.5 mg/kg/day) +/- itraconazole regimen

HSCT, hematopoietic stem cell transplant; SOT, solid organ transplant; BAL, bronchoalveolar lavage; CGD, chronic granulomatous disease; COPD, chronic obstructive pulmonary disease; CSF, cerebral spinal fluid; BAL, bronchoalveolar lavage; NTM, non-tuberculous mycobacteria.

^aSpecific algorithm for patients with influenza associated pulmonary aspergillosis by Verweij et al. (2020).

Fungal rhinosinusitis due to *Aspergillus* species present as different entities showing similarities with pulmonary aspergillosis. Acute invasive aspergillosis sinusitis, occurring in severely immunocompromised hosts (see section "The spectrum of aspergillosis"), is characterized by bone lysis on CT-scan, and bone and sinus tissue invasion by hyphae on biopsy. In non-immunocompromised patients, simple aspergilloma from odontogenic origin may develop in the maxillary sinus cavity. Allergic fungal sinusitis, reported in patients with atopy, is characterized by chronic pansinusitis resistant to antibiotic therapy, nasal polyposis, without bone involvement on CT-scan, and without bone hyphae invasion on biopsy (deShazo et al., 1997; Lafont et al., 2017).

Biology, pathogenesis and virulence factors of *Aspergillus* species

Aspergillus conidia have an outer layer composed of hydrophobins (forming a rodlet layer) and melanin (Aimanianda et al., 2009; Paris et al., 2003; Valsecchi et al., 2019). The rodlet layer contributes to the hydrophobicity of the conidia, which in turn contribute to their airborne nature (Grünbacher et al., 2014). In *A. fumigatus*, there are seven hydrophobins (RodA-G), but only the most expressed one, RodA, was shown to be responsible for rodlet formation (Valsecchi et al., 2017). In *A. nidulans*, there are six hydrophobins (RodA and DewA-E), but only the deletion of RODA results in the loss of rodlet layer (Grünbacher et al., 2014). Among other *Aspergillus* species, several putative hydrophobin genes have been reported (Littlejohn et al., 2012; Pel et al., 2007), but are not well characterized.

The melanin pigment, synthesized by a cluster of genes, gives the conidia the color of bluish green, and protects the cell from environmental stresses, such as ultraviolet light (Geib et al., 2016). The color of the conidia of different *Aspergillus* conidia varies due to the different melanin composition resulting from corresponding melanin biosynthetic pathways (Fig. 2). For instance, 1,8-dihydroxynaphthalene-melanin (DHN-melanin) is present in *A. fumigatus* and *A. terreus*, while 3,4-dihydroxyphenylalanine-melanin (DOPA-melanin) is found in *A. flavus*, *A. niger* and *A. nidulans* (Pal et al., 2014).

Upon swelling, outer rodlet-melanin layers disappear and the inner cell wall, composed of different polysaccharides (chitin, β -1,3-glucan, α -1,3-glucan and galactomannan), is exposed. Upon germination, a polysaccharide (galactosaminogalactan) specific to *Aspergillus* mycelia is synthesized (Fontaine et al., 2011). Galactomannan (GM) and galactosaminogalactan (GAG) are heteropolysaccharides; GM is composed of mannan backbone with galactofuranose side-chains (Latge et al., 1994), while GAG is composed of galactose, galactosamine (GalN) and *N*-acetyl-galactosamine (GalNAc) (Fontaine et al., 2011; Lee et al., 2016).

Aspergillus species possess various virulence factors which facilitate its pathogenesis which will be described in the following.

Hydrophobins and other surface proteins

The dormant conidia of *Aspergillus* species are covered by a rodlet layer, which are immunologically inert (Aimanianda et al., 2009). Its masking of the underlying immunogenic polysaccharides in the inner cell wall immunologically silence the dormant conidia, and thus, enhances fungal survival in vivo (Carrion Sde et al., 2013). Distortion or absence of rodlet layer facilitate the conidial phagocytosis by the immune cells, confirming its role in evasion from immune recognition (Aimanianda et al., 2009; Dagenais et al., 2010). Proteomic analysis revealed that, besides the highly abundant hydrophobins, the conidial surface includes various proteins. For example, the CcpA protein has also been described to minimize innate immune response (Voltersen et al., 2018). Some conidial surface proteins act as allergens, such as Asf 3 (Asif et al., 2006), that are associated to the allergic form of aspergillosis (ABPA or SAFS).

Fig. 2 Macroscopic and microscopic images of different pathogenic *Aspergillus* species. (A) *A. fumigatus*, (B) *A. flavus*, (C) *Aspergillus* section *Nigri*, (D) *A. nidulans*, (E) *A. terreus*. The species-specific conidial melanins contribute to the varying color across the *Aspergillus* species. Additionally, the conidial size also varies; In diameter, *A. fumigatus* 2–3.5 μm , *A. flavus* 3–6 μm , *A. niger* 4–5 μm , *A. terreus* 1.5–2 μm (Bengyella et al., 2017; Koch et al., 2019; Pasqualotto, 2009). Courtesy of the French National Reference Center for Invasive Mycoses and Antifungals (CNRMA).

Melanin

Fungal melanin has been considered as an important virulence factor. Of note, different melanin (predominantly DHN-melanin and DOPA-melanin) has been found across various *Aspergillus* species (Pal et al., 2014). DHN-melanin has been reported to interfere with the intracellular killing mechanisms by inhibiting the acidification of phagolysosome (Amin et al., 2014; Thywissen et al., 2011) and quenching reactive oxygen species (Jahn et al., 2000). In addition, melanin also inhibits LC3-associated phagocytosis by calcium sequestration (Akoumianaki et al., 2016; Kyrmizi et al., 2018). Melanin-deficient conidia induce significantly more proinflammatory cytokines as compared with the wild-type conidia in a lectin receptors dependent manner, suggesting that, like hydrophobins, melanin also participates in masking the immunogenic polysaccharide in the inner cell wall (Chai et al., 2010a). DOPA-melanin of *A. nidulans* was shown to inhibit nitric oxide and TNF- α production (Gonçalves Rde et al., 2013), suggesting that DOPA-melanin of pathogenic *Aspergillus* species could modulate the host immune response. On the other hand, *A. terreus* lacks naphthopyrone synthase, which is highly conserved among *Aspergillus* species (Gressler et al., 2015; Zaehle et al., 2014); the cinnamon-brownish pigment formed in *A. terreus* is independent of tyrosine or L-DOPA supplementation (Eisenman and Casadevall, 2012). In contrast to other *Aspergillus* species, *A. terreus* pigment is of 4-hydroxyphenylpyruvate origin (Geib et al., 2016). Nevertheless, *A. terreus* conidia were shown to persist inside macrophages and dendritic cells without inhibiting phagolysosome acidification, contributing to its reported higher dissemination rate and lower response to antifungal treatment than *A. fumigatus* (Hsieh et al., 2017).

Galactosaminogalactan

Galactosaminogalactan (GAG) is an *Aspergillus*-specific polysaccharide, which is a linear heterogenous polysaccharide composed of randomly distributed units of α -1,4-linked galactose, galactosamine (GalN) and *N*-acetyl-galactosamine (GalNAc) (Fontaine et al., 2011; Lee et al., 2016). GAG has been considered as virulence factor of *Aspergillus* species due to its anti-inflammatory properties, by inducing the cytokine IL-1Ra (Fontaine et al., 2011; Gresnigt et al., 2014), and by masking mycelial pro-inflammatory polysaccharide β -1,3-glucan (Gravelat et al., 2013). GAG also mediates virulence by resisting the antifungal activity of neutrophil extracellular traps (Lee et al., 2015). Furthermore, soluble GAG (with less amount of GalNAc) has been shown to promote neutrophil apoptosis via natural killer cells (Robinet et al., 2014). Besides being associated to the mycelial surface, GAG is also secreted by *Aspergillus* mycelia. Mycelial surface GAG or GAG secreted from *A. fumigatus* and *A. flavus* are capable of activating platelet, and thus, causing excessive inflammation, thrombosis and thrombocytopenia (Deshmukh et al., 2020; Rambach et al., 2015).

Iron acquisition

Iron is essential for microbial growth, and pathogenesis depends on the sequestration of iron from the host. For *Aspergillus*, iron has been shown to be a major determinant for its invasive growth in the host (Hsu et al., 2018). The siderophore-mediate iron uptake is essential in maintaining fungal growth in iron-limited environment in the host, and thus, is crucial for the virulence of *Aspergillus* (Hissen et al., 2004; Schrettl et al., 2004). Deleting the siderophore biosynthetic gene *SidA* and bZIP-type regulator (Schrettl et al., 2010) (required for transcriptional remodeling under iron starvation in *A. fumigatus*) rendered the fungi avirulent in a mouse infection model (Hissen et al., 2005).

Secreted proteases/allergens

Aspergillus secrete proteases to degrade factors involved in host antifungal immunity. The proteins Alp1 (Behnsen et al., 2010) and Mep1 (Shende et al., 2018) secreted by *A. fumigatus* degrade complement proteins C3, C4 and C5 (see section “Complement activation” for the importance of complement system against *Aspergillus*). Alp1 is found oversecreted in the exoproteome of *A. flavus* isolates from cornea, suggesting its possible role in the establishment of keratitis (Selvam et al., 2015). Another secreted allergen of *A. fumigatus*, enolase (Eno1), recruits complement regulators and plasmin, thus controlling complement activation and resulting in epithelial cell damage, respectively (Dasari et al., 2019).

Mycotoxins

Mycotoxins are secondary metabolites produced by fungi that are capable in causing diseases. Aflatoxin produced by *A. flavus* and *A. parasiticus* is among the mycotoxins that have received attention due to its impact on agricultural foodstuff (El Khoury et al., 2011; Sarma et al., 2017). Intake of food that is contaminated by aflatoxin, which is carcinogenic and mutagenic, could cause stunted growth in children, liver damage or cancer. Nevertheless, aflatoxin has not been shown to be associated to the pathogenesis of aspergillosis, and thus, is not considered a virulence factor. Gliotoxin is an immunosuppressive mycotoxin found in *A. fumigatus*, demonstrating cytotoxic effects to macrophage-like cells and T cells (Kupfahl et al., 2006), and is associated with apoptosis of leukocytes at the foci of infection in murine model of aspergillosis (Liu et al., 2018). The deletion of the gliotoxin gene *gliP* attenuates virulence in non-neutropenic murine infection model, but not the neutropenic model (Spikes et al., 2008; Sugui et al., 2007).

Host-immunology against *Aspergillus*

Upon inhalation, the *Aspergillus* conidia are instantly encountered by the host innate immunity. The two major arms of innate immunity, cellular and humoral immunity, synergistically elicits antifungal properties for efficient clearance of these fungal

pathogens. The absence or malfunctions of one or more components in this host-defense, as observed in immunocompromised population, could lead to aspergillosis.

Innate immunity

Cellular-mediated immunity

Cellular-mediated immunity is crucial in eliminating the fungal pathogen. The inhaled conidia are cleared by intracellular killing mechanisms, while the hyphae are generally managed extracellularly. The intracellular killing in phagocytes depends on oxidative burst triggered by conidial swelling. Chronic granulomatous disease (CDG) patients are prone to aspergillosis due to the defective oxidative burst in their phagocytes caused by mutation in NADPH oxidase, resulting in the inability to kill *Aspergillus* conidia. Iron-sequestration by secreted lactoferrin is an alternate to check fungal growth, as iron is essential for fungal growth. In response to *Aspergillus*, the immune cells also secrete various cytokines and chemokines to recruit and enhance the immune effector functions.

Macrophages and neutrophils

Upon inhalation and reaching the distal alveoli, the conidia are likely to encounter the resident alveolar macrophages. As a primary phagocyte, macrophages readily phagocytose the inhaled conidia, traffic the conidia to phagolysosomal compartment through endocytic pathway and then intracellularly through respiratory oxidative burst (Philippe et al., 2003; Sun et al., 2014). The alveolar macrophages also secrete cytokines to mediate an inflammatory response and chemokines to recruit other immune effector cells, most importantly, neutrophils (Grazziutti et al., 1997; Pylkkanen et al., 2004). Neutrophils are important immune cells for host defense against aspergillosis, as neutropenia is one of the main risk factors for invasive aspergillosis. Beside oxidative intracellular killing of conidia, neutrophils are also capable in inhibiting conidial growth, through oxidative burst-independent mechanism, by lactoferrin-mediated iron depletion as iron is essential for *Aspergillus* mycelial growth (Zarembek et al., 2007).

In the case where the phagocytes are unable to kill the intracellular conidia, germination will take place. *Aspergillus* mycelia are too large to be phagocytosed. Extracellular antifungal strategies against mycelia are mainly imposed by neutrophils, through neutrophil extracellular traps (NETs). While NETs are fungicidal against other medically important fungal pathogens, they impose fungistatic activity on *Aspergillus* species instead (Bruns et al., 2010; McCormick et al., 2010). The extracellular destruction of mycelia by neutrophils requires mycelial opsonization by antibody and mediation of Fc- γ receptors, triggering the production of toxic reactive oxygen species (Gazendam et al., 2016). The constituents in *Aspergillus*-induced NETs responsible for fungal growth inhibition are not fully elucidated. Calprotectin, a zinc ion chelator that is present in NETs, was demonstrated to be responsible for NETs-mediated fungal growth inhibition (McCormick et al., 2010). Importantly, NETs also have contradictory role in which it could obstruct fungal clearance in vivo. Inhibiting NETosis in vivo results in less lung injury in IPA mouse model (Alflen et al., 2020).

Dendritic cells

Dendritic cells (DCs) contributed to host defense through internalization of conidia or hyphae via pattern recognition receptors, secretion of cytokines, migration to draining lymph nodes after activation, and regulate T cells polarization (Bozza et al., 2002). DCs interact and internalize *A. fumigatus* conidia through the C-type lectin receptor dendritic cell-specific ICAM-3-grabbing nonintegrin (DC-SIGN) through the galactofuranose moiety of galactomannan, resulting in the induction of pro-inflammatory cytokines (Chiodo et al., 2014; Serrano-Gomez et al., 2004, 2005). DCs can also be activated by α -1,3-glucan partly through TLR2 (Stephen-Victor et al., 2017) and by β -1,3-glucan through Dectin-1 (Mezger et al., 2008). The cross-talk between neutrophils and DCs in response to *Aspergillus* germ tubes promotes the activation and efflux of DCs (Park et al., 2012). Upon *Aspergillus* infection, DCs release CXCL8, responsible for recruitment of neutrophils (Gafa et al., 2007). *Aspergillus*-infected DCs express CCR7 receptor (Gafa et al., 2006), release soluble factors that induce the expression of CD11b and CD18 (complement receptor 3, see section "Membrane-bound PRRs") on neutrophils, express cytokines for migration of memory T cells (CCL3, CCL4, CXCL10 and CCL20) and for migration of CCR7+ naïve T cells and mature DCs in the lymph nodes (CCL19) (Gafa et al., 2007).

Notably, different subsets of DCs display distinct effector functions against *A. fumigatus*. Myeloid DCs and monocyte-derived DCs phagocytose *A. fumigatus* conidia and germ tubes by the receptors TLR2, TLR4 and Dectin-1, while plasmacytoid DCs (pDCs) do not mediate phagocytosis of the fungus and do not express Dectin-1 (Lothar et al., 2014). Instead, pDCs recognize and bind to *A. fumigatus* hypha through the receptor Dectin-2, which then mediates the expression of cytokines TNF- α and IFN- α , and the formation of pDC extracellular traps (Loures et al., 2015), partly through gliotoxin production (*A. fumigatus*-specific mycotoxin) (Ramirez-Ortiz et al., 2011). The importance of pDC against IA is also validated in the higher susceptibility in pDC-depleted mouse infection model (Loures et al., 2015; Ramirez-Ortiz et al., 2011).

Natural killer cells

Patients with severe invasive aspergillosis have lower natural killer (NK) cell counts than those with well-controlled invasive aspergillosis (Stuehler et al., 2015). Depleting NK cells contributed to higher mortality and fungal burden in murine model of invasive aspergillosis (Morrison et al., 2003). *A. fumigatus* hypha, but not resting conidia, activate NK cells (Schmidt et al., 2011). In turn, NK cells are capable of killing the hypha, but not the resting conidia, through perforin-mediated cytotoxicity (Schmidt et al., 2011). NK cells also mediate anti-*Aspergillus* activity by releasing cytokines IFN- γ and GM-CSF (Bouzani et al., 2011; Park et al., 2009; Ziegler et al., 2017). IFN- γ and GM-CSF are important cytokines contributing to resistance to aspergillosis (see details in

section “Adaptive immunity”). CD56 (specific receptor on NK cells) has been shown to interact with *Aspergillus* mycelia (Ziegler et al., 2017), for which the ligand(s) remain unknown. Neutropenic mice infected with *A. niger* showed NK cell proliferation, inhibiting fungal growth (Benedetto et al., 1988).

Platelets

Although *Aspergillus* species is rarely found to be circulating in the bloodstream, thrombocytopenia (low platelet counts), which often coincides with neutropenia, has been suggested to be a risk factor for invasive aspergillosis (Bae et al., 2020). In vitro, platelets do not internalize conidia, but surround and aggregate around them (Perkhofer et al., 2008). Platelet activation by conidia is suggested to be mediated by the surface melanin, in the case of *A. fumigatus* (Rambach et al., 2015), which in turn attenuates germination and induces conidial phagocytosis and killing by neutrophil (Perkhofer et al., 2008; Tischler et al., 2020). On the other hand, platelets adhere to the hypha of *Aspergillus* species and are activated by the cell wall polysaccharide, galactosaminogalactan (Deshmukh et al., 2020; Rambach et al., 2015). Activated platelets damage the *Aspergillus* hypha via granule-dependent mechanisms, which attenuate hyphal elongation and viability (Christin et al., 1998; Perkhofer et al., 2008, 2015). In thrombocytopenic mice intranasally infected by *Aspergillus*, the increased mortality is contributed by excessive inflammation and severe lung hemorrhage, without significant differences in neutrophil phagocytosis or hyphal growth, suggesting that although platelets play a minor role in anti-*Aspergillus* defense, it is crucial for survival by maintaining lung homeostasis in response to extensive inflammation during aspergillosis (Tischler et al., 2020).

Respiratory epithelial cells

The respiratory epithelial cells are not professional phagocytes, but instead, assist in the host antifungal defense. Airway epithelial cells are capable to internalize conidia and bind to *Aspergillus* mycelia, only low levels of cytokines are induced, in the absence of serum (Zhang et al., 2005). But they release antimicrobial peptide like β -defensin upon contact with *Aspergillus* (Alekseeva et al., 2009). Meanwhile, in the presence of serum, bronchial epithelial cells release IL-8, a chemokine recruiting neutrophils, upon contact with mycelia but not conidia (Balloy et al., 2008).

Mast cells, basophils and eosinophils

The immune effectors contributing to allergic bronchopulmonary aspergillosis (ABPA) are predominantly mast cells, basophils and eosinophils, which otherwise do not contribute any protective role against aspergillosis (Agarwal et al., 2011; Gernez et al., 2016). *Aspergillus* allergen-specific IgE binds to mast cells and basophils, causing the release of inflammatory mediators, such as histamine, that contribute to allergic reactions (Madan et al., 1997b); nevertheless, circulating basophils are not professional antigen presenting cells (Sharma et al., 2013). Beside its role in allergic reactions to *Aspergillus*, mast cells could also mediate detrimental effect on lung function. Comparing to *A. flavus*, *A. niger* and *A. nidulans*, the *A. fumigatus* hypha, but not the resting conidia, are significantly more capable in activating the degranulation of mast cells in an IgE-independent manner, resulting in decline in lung function due to aggravation of inflammation and airway obstruction (Urb et al., 2009). Repeated exposure of *Aspergillus* conidia leads to influx of eosinophils into the lung (Murdock et al., 2011). Eosinophilia (elevated count of eosinophils) is observed in murine model of ABPA, as well as in human ABPA patients (Agarwal et al., 2011; Kurup et al., 1992). In response to *Aspergillus*, eosinophils release extracellular traps that have neither killing nor fungistatic activity against the fungus (Muniz et al., 2018).

Humoral immunity

The anti-*Aspergillus* activity of humoral immunity has always been overshadowed by the cellular immunity. In fact, it constitutes an essential arm of host immune defense against aspergillosis. A myriad of humoral factors has been found to interact with *Aspergillus* conidia or mycelia. Examples include the complement system, C-type lectins, antimicrobial peptide and antibodies.

Complement activation

The complement system comprises of three activation pathways (classical, lectin and alternative) regarding the different starting complexes. The three activation pathways all lead to the production of C3 convertase that activates C3 into C3b, which is an opsonin that binds to pathogen surface. C3b also participates in the production of C5 convertase, transforming C5 into C5b, which then polymerize with C6, C7, C8 and C9 to form membrane attack complex (MAC). The formation of MAC on microbial surface causes death of the microbe through lysis. In case of *A. fumigatus*, the formation of MAC on the dormant conidial surface was not observed (Wong et al., 2020a). Instead, C3b opsonizes *A. fumigatus* dormant conidia and mycelia (Kozel et al., 1989; Sturtevant and Latgé, 1992), and facilitates phagocytosis through CR3 and CR4 (Braem et al., 2015; Wong et al., 2020a). In *A. fumigatus*, RodA in the conidial surface rodlet layer has been shown to be the ligand for C3b binding (Wong et al., 2020a), while C3-fragments have also been shown to be deposited on the melanin-ghosts obtained from *A. niger* conidia (Rosas et al., 2002).

Antimicrobial peptides

Antimicrobial peptides (AMPs) are naturally occurring peptides, often cationic and amphipathic, that control infections and modulate inflammation. Direct antifungal effect of AMPs on *Aspergillus* has not been clearly demonstrated. However, peptides of human lactoferrin and histamine-5 demonstrated activity in damaging hypha of *A. fumigatus* (Lupetti et al., 2008). Human β -defensins secreted by airway epithelial cells in response to *A. fumigatus* are associated to the activation-maturation of DCs, as well as stimulation of pro-inflammatory cytokines from DCs (Alekseeva et al., 2009; Presicce et al., 2009). In chronic rhinosinusitis

patients, lysozyme has been reported to show fungicidal activity against different fungal species (Woods et al., 2011). LL37, a human cathelicidin antimicrobial peptide, could directly bind to *A. fumigatus* surface showing mycelial growth inhibition in vitro (Luo et al., 2019).

Pattern recognition receptors (PRRs) of *Aspergillus*

Pattern recognition receptors (PRRs) recognize the structurally conserved pathogen associated molecular patterns (PAMPs) associated with microbes, and thus, are crucial in mediating the proper clearance of the invading pathogens through the corresponding downstream signaling. PRRs are present in immune cells as well as various other cell types not typically involved in immunity, and are membrane-bound or secreted in soluble forms.

Membrane-bound PRRs

Membrane-bound PRRs are mainly composed of two classes: Toll-like receptors (TLRs) and C-type lectins receptors (CLRs). Both TLRs and CLRs are involved in the immune recognition of *Aspergillus*. Other membrane-bound PRRs, such as complement receptors, are also crucial for host defense against *Aspergillus*.

TLRs: Among the TLR family, the crucial role of TLR2 and TLR4 in immune response against *Aspergillus* has been implicated for *A. fumigatus*, *A. flavus*, *A. niger*. Knockout of TLR2 rendered higher mortality in murine model of invasive aspergillosis (Balloy et al., 2005). In human, the polymorphisms in TLR2, TLR4 or TLR9 are associated to the susceptibility to severe asthma with fungal sensitization (Carvalho et al., 2008). TLR2 is associated to conidial phagocytosis, macrophage activation, neutrophil recruitment and production of proinflammatory cytokine (particularly, TNF- α) in response to *A. fumigatus* and *A. niger* (Balloy et al., 2005; Luther et al., 2007; Mambula et al., 2002; Meier et al., 2003), whereas transcriptional expressions of PRRs including TLR2, TLR4 and TLR9, are increased in corneal ulcers by *A. flavus* (Karthikeyan et al., 2011). Zymosan (repeating units of glucose connected by β -1,3-glycosidic linkage) is one of the ligands for TLR2, suggesting that *Aspergillus* β -1,3-glucan could be recognized by TLR2. By experimental data, β -1,3-glucan and galactomannan are suggested to be recognized by TLR4, while α -1,3-glucan is recognized by both TLR2 and TLR4 (Chai et al., 2011; Stephen-Victor et al., 2017).

The TLRs activate the MyD88-dependent pathway, thus, activating the nuclear factor kappa B (NF- κ B)-mediated anti-*Aspergillus* inflammatory responses (Bretz et al., 2008; Mambula et al., 2002). Additionally, in response to *Aspergillus*, the release of IL-12 and IL-6 (the anti-*Aspergillus* cytokines) by dendritic cells are also shown to be dependent on TLR2 and TLR4, respectively (Braedel et al., 2004).

CLRs: Through their carbohydrate recognition domains, the CLRs play a central role in immune recognition of fungal pathogens that are covered by polysaccharide-rich cell wall. Several membrane-bound CLRs have been reported to associate with *Aspergillus* species, including Dectin-1, Dectin-2, mannose receptor, DC-SIGN, and MelLec.

The β -1,3-glucan receptor Dectin-1 plays an important role in recognizing fungal pathogens, including *Aspergillus* species (Steele et al., 2005). The level of Dectin-2, that recognizes mannan on *A. fumigatus* hypha, is elevated during *Aspergillus* invasion (Loures et al., 2015; Sun et al., 2013). Dectin-2 is present on immune cells that also express mannose receptor (Sun et al., 2013). Both mannose receptor and DC-SIGN recognize *Aspergillus* galactomannan, mediate phagocytosis of pathogens and promote antigen presentation (Bennett et al., 1987; Chiodo et al., 2014; Serrano-Gomez et al., 2004, 2005). Mincle, expressed by immune cells of myeloid origin interacts with *A. fumigatus* causing keratitis (Lin et al., 2017; Zhao et al., 2017), but its role against invasive infection need to be studied. Exceptionally, the CLR MelLec has been discovered to recognize, not cell wall polysaccharide, but the DHN-melanin on the cell wall of *A. fumigatus* (Stappers et al., 2018). CD23, another CLR, interacts with *A. fumigatus* through α -mannan and β -glucan (Guo et al., 2018).

Complement receptors (CRs): As mentioned in section “Complement activation”, complement activation leads to opsonization of *Aspergillus* conidia and hypha by C3b and iC3b (the inactivated form). CR3 (CD11b/CD18) and CR4 (CD11c/CD18) are heterodimers that share a common subunit of CD18, recognize the opsonized *Aspergillus* and facilitate phagocytosis (Braem et al., 2015; Wong et al., 2020a). Opsonization by iC3b is mainly recognized by CR4, while CR3 recognize a range of ligands, including iC3b, β -1,3-glucan and pentraxin-3 (a soluble PRR, refer to section “Soluble PRRs”) (Bose et al., 2013; Moalli et al., 2010; Myones et al., 1988). Meanwhile, CR1 recognizes C3b, C1q and mannose binding lectin (soluble PRRs, please refer to section “Soluble PRRs”) (Fallman et al., 1993; Ghiran et al., 2000; Klickstein et al., 1997).

Fc- γ receptors: Fc γ receptors demonstrate protective role against *Aspergillus* opsonized by pentraxin-3, or *Aspergillus*-specific antibodies, through facilitation of phagocytosis and oxidative burst (Becker et al., 2016; Moalli et al., 2010; Zhou and Brown, 1994).

Others: CD56 (specific receptor on NK cells) has been shown to interact with unknown ligand(s) on *Aspergillus* mycelia, and is responsible for activation of NK cells (Ziegler et al., 2017). Calreticulin (CALR) in association with CD91 (CALR-CD91 complex) has been reported to mediate *A. fumigatus* conidial phagocytosis through surfactant protein D (SP-D) (Vandivier et al., 2002). NOD2 has been reported to interact with *A. fumigatus*, and their interaction results in the NF- κ B activation; nevertheless, NOD2 deficiency do not increase the susceptibility to invasive aspergillosis (Li et al., 2012; Ogura et al., 2001).

Soluble PRRs

Collectins: Collectins are soluble C-type lectins with a collagenous region and a carbohydrate recognition domain. Collectins contributing to protective role of aspergillosis include surfactant proteins, and mannose binding lectin.

Surfactant proteins SP-A and SP-D are produced in the lungs and are involved in innate immune system. Both SP-A and SP-D have been demonstrated to bind to *A. fumigatus* conidia and mycelia and enhance the effector functions of neutrophils and

macrophages (Geunes-Boyer et al., 2010; Madan et al., 1997a, 2001; Wong et al., 2018). SP-D binds to the melanin of *A. fumigatus* conidia and to galactomannan and galactosaminogalactan on *A. fumigatus* mycelia (Wong et al., 2018), while the ligands of SP-A is unidentified.

Mannose-binding lectin (MBL), a starting complex of the lectin pathway in the complement system, binds to *A. fumigatus* and provides a protective role in murine model of invasive pulmonary aspergillosis (Kaur et al., 2007). Deficiency in MBL are demonstrated to be associated to acute invasive aspergillosis (Lambourne et al., 2009).

Others: The long pentraxin-3 (PTX3) is an important humoral factor against *A. fumigatus*. PTX3 binds to *A. fumigatus* dormant conidia and mycelia (Garlanda et al., 2002). Polymorphism in the PTX3 gene leads to impaired neutrophil antifungal functions and thus, higher susceptibility to invasive aspergillosis (Garlanda et al., 2002). Galectin-3, a β -galactoside binding lectin, binds to the conidia and hypha of *A. fumigatus* and is associated to neutrophil recruitment to the site of infection (Snarr et al., 2020).

Adaptive immunity

After phagocytosis of pathogens, antigen presenting cells (APCs) migrate to the draining lymph nodes where they present antigens to naïve T cells through major histocompatibility complex (MHC) molecules. The PAMPs of *Aspergillus* shape the differentiation of T cells subsets and B cells to mediate host inflammation and antibody response.

T cells

The susceptibility to aspergillosis is suggested to correlate with the preferential induction of the subsets of CD4⁺ helper T cell (Th), Th1 versus Th2, through pattern of induced cytokines. The mechanisms driving the differentiation of *Aspergillus*-specific T helper cells into Th1 or Th2 cells depend on multiple factors from the host and the pathogens. In general, live conidia induce Th1 response, while inactivated conidia or non-viable *Aspergillus* antigens (culture filtrate or crude mycelial extract) promote Th2 response (Grazziutti et al., 1997; Koth et al., 2004; Rivera et al., 2005). The signature cytokines of Th1 cells (IFN- γ , TNF- α , GM-CSF, IL-2, IL-12, etc.) are crucial in anti-*Aspergillus* activity by activating macrophages. Adoptive transfer of IFN- γ producing *Aspergillus*-specific T helper (Th) cells have been suggested to provide protective role for the host against aspergillosis (Beck et al., 2006; Cenci et al., 2000). Inhibiting or lower levels of IFN- γ or TNF- α results in increased mortality associated with higher fungal burden in immunocompetent and immunocompromised murine model of aspergillosis (Cenci et al., 1998; Mehrad et al., 1999; Nagai et al., 1995). In human, lower secretion of IFN- γ has been shown to be associated with higher risk of chronic aspergillosis in the specific context of STAT3 deficient patients (Danion et al., 2020).

In contrast, the Th2 response cytokines (IL-4, IL-5 and IL-10, etc.) have detrimental effect on the host against invasive aspergillosis, and support the pathogenesis of allergic bronchopulmonary aspergillosis (ABPA) (Cenci et al., 1998; Skov et al., 1999). IL-10 is associated with down-regulation of Th1 response and macrophage activation, which then contribute to higher susceptibility for invasive aspergillosis in mice (Clemons et al., 2000; Roilides et al., 2001). Gene polymorphisms of IL-10 predispose cystic fibrosis patients to *Aspergillus* colonization and ABPA (Brouard et al., 2005; Casaulta et al., 2003). Cystic fibrosis patients with ABPA have elevated levels of IL-4 and IL-5, which are responsible for eosinophilia (Kurup et al., 1997; Murali et al., 1993; Skov et al., 1999).

Even though studies suggested that Th17 cells either do not play any role against *Aspergillus* or may have detrimental role (Chai et al., 2010b; Zelante et al., 2007), they are involved in the migration, recruitment and activation of neutrophil granulocytes to the site of infection, and therefore suspected to play a role against *Aspergillus*. *Aspergillus* is also known to drive Th17 response via dendritic cell stimulation and IL-23 production (Wong et al., 2019), and in turn this Th17 activation depends upon recognition of *Aspergillus* cell wall polysaccharide β -glucan by Dectin-1 (Armstrong-James et al., 2017). Both in infectious aspergillosis and allergic conditions due to *Aspergillus*, a higher expression of IL-17 has been reported (De Luca et al., 2017; Fukahori et al., 2014; Zelante et al., 2015).

Regulatory T cells (Treg), another distinct subset of T cells, are important in regulating the inflammatory response induced by *Aspergillus* through the expression of indoleamine 2,3-dioxygenase (Bacher et al., 2014; Montagnoli et al., 2006; Paveglia et al., 2011). Dendritic cells primed by *A. fumigatus* α -1,3-glucan stimulates the differentiation of naïve T cells into Treg cells through programmed death-ligand 1 (PD-L1) (Stephen-Victor et al., 2017).

CD8⁺ cytotoxic T cells are responsible in direct killing of host cells infected with intracellular pathogens. Although such direct killing is not described, *Aspergillus*-specific CD8⁺ T cells are found in human, with unclear roles (Chaudhary et al., 2010; Cui et al., 2013).

B cells and antibody

B cells are not directly involved in orchestrating anti-*Aspergillus* immune response, as shown in the resistance to aspergillosis in B cell-deficient mice with increased Th1-mediated response (Montagnoli et al., 2003). However, B cells are essential in generating regulatory T cells and *Aspergillus*-specific antibodies (Montagnoli et al., 2003).

Owing to the immunocompromised status, antibody response to *Aspergillus* is generally undetectable in the sera of patients during the course of invasive aspergillosis (Young and Bennett, 1971). However, patients recovering from invasive aspergillosis have increased titer of *Aspergillus*-specific antibodies that is associated with good prognosis. In other forms of aspergillosis in otherwise immunocompetent patients, such as aspergilloma, ABPA and CPA, *Aspergillus*-specific antibodies are present in the patient sera.

These antibodies are specific to *Aspergillus* proteins or polysaccharides, and have been studied for their diagnostic potentials (Kazakova et al., 2020; Komarova et al., 2018; Sarfati et al., 2006; Wong et al., 2020b).

Clinical aspects of aspergillosis

Diagnosis and diagnostic tools available

Clinical and radiological features

IPA usually presents as non-specific bronchopneumonia with cough, sputum production, dyspnea and fever unresponsive to antibiotics. Pleuritic chest pain and hemoptysis are important clinical signs of IPA that may be observed due to pulmonary infarction. Computed tomography (CT)-scan identifies early stages of the disease which includes nodules, consolidative lesions and wedge-shaped infarcts. The main radiological characteristic of IPA is the "halo sign": a central nodule surrounded by ground-glass opacity representing hemorrhage (Fig. 3). It is mainly seen in neutropenic patients early in the course of infection (first week). However, the halo sign is not specific of IPA and can be observed in all invasive mold infection as well as some bacterial pneumonitis. A later radiological sign is the air crescent sign, secondary to nodule necrosis and cavitation (Kousha et al., 2011). Bergeron et al. described two different radiological patterns depending on the type of immunosuppression; (1) Nodule with a halo sign revealed angioinvasive aspergillosis in neutropenic patients with acute leukemia, (2) Centrilobular nodules, bronchiolitis with tree-in-bud opacities revealed airway-invasive aspergillosis in non-neutropenic with chronic lymphoproliferative disorders, stem cell and solid organ transplant recipients receiving steroids (Bergeron et al., 2012).

Patients with CPA usually present with constitutional symptoms including weight loss, malaise, sweats and non-specific pulmonary symptoms (chronic productive cough, breathlessness, chest discomfort and sometimes hemoptysis). Radiological findings depend on the subtype of CPA (Godet et al., 2016). Aspergilloma is the morphological appearance of a fungus-ball composed entirely of fungal hyphae and extracellular matrix in a preexisting pulmonary cavity or an ectatic bronchus (Denning et al., 2016). It may be associated with all form of CPA. For CCPA, CT-scan shows single or multiple cavities, with enlargement of cavity wall thickness. Extensive fibrosis with fibrotic destruction of at least two lobes of lung characterize CFPA and leads to a major loss of lung function. *Aspergillus* nodules (<3 cm) are an unusual form of CPA, frequently misdiagnosed as it mimics many differential diagnosis (i.e., lung cancer and metastases, rheumatoid nodules, etc.). Subacute invasive pulmonary aspergillosis is characterized on CT-scan by nodules with cavitation, consolidation, and lung tissue invasion by hyphae on biopsy (Denning et al., 2016).

Clinical symptoms of ABPA include poorly controlled cortico-dependent asthma with recurrent pulmonary exacerbation (cough, wheeze, shortness of breath), sub-acute deterioration of lung function, and expectoration of mucus plugs with or without

Fig. 3 Categories of pulmonary aspergillosis. ABPA, allergic bronchopulmonary aspergillosis; CCPA, chronic cavitary pulmonary aspergillosis; CF, cystic fibrosis; CFPA, chronic fibrosing pulmonary aspergillosis; IPA, invasive pulmonary aspergillosis.

fever (Greenberger et al., 2014; Tracy et al., 2016). CT-scan usually display central bronchiectasis and bronchial wall thickening. Excessive mucus production appears as mucoid impaction. Hyper-attenuating mucoid impaction on high-resolution CT-scan may be considered as a pathognomonic radiographic finding and observed in 20% of patients (Agarwal et al., 2007) (Fig. 3).

New imaging based-technique may have the potential to make the diagnosis and locate the site of infection. Positron emission tomography (PET)-scan either combined to monoclonal antibody JF5 that binds to a secreted glycoprotein during hyphal invasion or coupled with Gallium-68 fungal siderophore taken by the fungus if present may be of great help and overcome the problem of specificity faced by CT and PET scans (Herrera and Husain, 2018; Savelieff and Pappalardo, 2017).

Microbiological diagnosis

Microbiological tools available to evidence *Aspergillus* in clinical samples are divided into (i) direct examination and histopathology of fresh and fixed sample, (ii) culture-based method, (iii) antigen detection (galactomannan and β -D-glucan), (iv) nucleic acid detection, and (v) serology (antibody detection). Although all may be useful for the diagnosis of aspergillosis, their sensitivity and specificity are highly variable depending on the type of aspergillosis.

For IPA, histopathologic, cytopathologic or direct examination of a specimen obtained by needle aspiration or biopsy in which hyphae are seen associated with tissue invasion constitute the gold standard mycological criteria (Donnelly et al., 2017). Antigen detection in blood, such as galactomannan, a cell wall constituent of *Aspergillus*, is considered a strong mycological criterion. However, sensitivity of this assay vary greatly among at-risk patients. Galactomannan has poor sensitivity in patients receiving mold-active prophylaxis and non-neutropenic patients (Zhou et al., 2017). Furthermore, galactomannan testing gives a number of false positive may be observed in patients receiving antibiotic, which production was contaminated with *Aspergillus* or in patient receiving enteral nutrition. False positive results may also be due to erroneous operational use of the kit or due to crossed reactions with some bacteria from the human microbiota. This can be explained by a poorer specificity of the monoclonal antibody design as it recognize much shorter oligosaccharide than initially thought (Krylov et al., 2019). Galactomannan may also be measured in bronchoalveolar lavage with a value of >1.0 optical density index for the diagnosis of IPA (Eigl et al., 2017). Although detection of *Aspergillus* DNA in blood samples is now included in consensual diagnostic criteria, results vary greatly among centers due to different sampling, extraction and PCR protocols (i.e., different target used, different primer efficiency, platforms and master mixes various efficacy) (White et al., 2011). β -D-Glucan test may be used to diagnose invasive aspergillosis but is less sensitive and specific owing to pan-fungal nature of this polysaccharide (Hoenigl et al., 2014). Accepted criteria are presented in Table 1 according to the latest updated consensus definitions of invasive fungal disease (Donnelly et al., 2019).

To diagnose CPA, an immunological response to *Aspergillus* (*A. fumigatus* IgG or precipitins) is a key diagnostic feature by allowing to differentiate infected from colonized patients. Isolation of *A. fumigatus* in sputum is not enough to make the diagnosis because it may only reflect colonization. Bronchoscopic specimens are more specific to diagnose infection but culture-positive rates are 56–81% (Denning et al., 2003; Nam et al., 2010). High level of galactomannan or *Aspergillus* DNA in respiratory fluids indicate high fungal burden and are complementary markers, however, no cut-offs value have been determined and *Aspergillus* PCR is highly variable among centers as stated previously (White et al., 2011). Antigens and nucleic acids detection in serum have poor sensitivity in immunocompetent patients.

Hypersensitivity to *A. fumigatus* is documented by a positive skin-test or high levels of *Aspergillus* specific IgE and IgG. Diagnosis of ABPA is made by satisfying a set of non-specific clinical, radiographic and serologic criteria (Agarwal et al., 2013).

Although diagnosis and management of aspergillosis has been improved in the last decades by biomarker assays, their limited accessibility and requirement for batch testing restrict their impact. The recent development of lateral flow assay will allow outside specialist center testing, provided performance is acceptable. Two commercial tests are currently available; to detect galactomannan, and the other, an extracellular glycoprotein (Pan et al., 2015; White et al., 2020). Research in novel biomarkers for aspergillosis diagnosis focus on metabolite-based detection. Indeed, fungal pathogens possess a rich metabolism resulting in a vast array of secondary metabolites, many species-specific. Latest emerging metabolite-based methods for aspergillosis detection include gliotoxin, siderophore and volatile compound in the breath of patients (Savelieff and Pappalardo, 2017). Other new methods propose the use of soluble mediators detection (pentraxin-3) and specific signature of cytokines for IPA that could both support diagnosis and predict outcome (Herrera and Husain, 2018).

Classifications and algorithm

Diagnosis of aspergillosis remains difficult, therefore classifications and algorithm have been developed by experts to ease and homogenize diagnostic practices. Invasive aspergillosis in immunocompromised patients is classified into proven, probable or possible aspergillosis depending on the strength of different clinical, radiological and microbiological criteria that may be seen in patients. These criteria were recently revised by the European Organization for Research and Treatment of Cancer and the Mycoses Study Group Education and Research Consortium (EORTC/MSG) (Donnelly et al., 2019). This classification requires host factors that are most often absent in critically ill patients. For this reason, specific algorithm were developed to diagnose IPA in critically ill patient (Blot et al., 2012) and modified to suit specific predisposing diseases such as severe influenza (Verweij et al., 2020). Consensual definition and diagnosis of the various forms of CPA were proposed by the European Society for Clinical Microbiology and Infectious Disease (ESCMID), European Confederation of Medical Mycology and European Respiratory Society (ERS) (Denning et al., 2016). This classification requires a combination of radiological evidence, direct evidence of *Aspergillus* infection or an immunological response to *Aspergillus* spp. and exclusion of alternative diagnoses (i.e., other fungal diseases, mycobacterial infection, lung carcinoma, etc.), all present for at least 3-months (Denning et al., 2016). Regarding ABPA and the spectrum of

disease that derives from *Aspergillus* hypersensitivity, most recent diagnostic and classification criteria were proposed by the ISHAM (international society for human and animal mycology) dedicated working group (Agarwal et al., 2013). These criteria include (i) a predisposing condition (asthma or cystic fibrosis), (ii) two mandatory criteria (elevated total IgE levels and specific IgE against *A. fumigatus*) and (iii) at least two other criteria among radiographic findings, eosinophilia and precipitins or IgG antibodies against *A. fumigatus* (Agarwal et al., 2013).

Treatment guidelines

Treatment of IPA should not be delayed for the establishment of diagnosis due to the rapid progression and high mortality rate of the disease. It relies on both antifungal agent prescription and improvement of immune status when possible. Voriconazole or isavuconazole are recommended first line treatment (Table 1) (Patterson et al., 2016; Ullmann et al., 2018). At this time there is no clear consensus about duration of therapy; however, a minimum of 6–12 weeks is recommended, depending on clinical severity. Prophylaxis against IPA is strongly suggested for high-risk patients with posaconazole or voriconazole (Maertens et al., 2018; Ullmann et al., 2018). Echinocandins should not be used as first line IPA treatment as randomized clinical trials comparing their efficacy with other antifungals are lacking (Aruanno et al., 2019). Also, *A. fumigatus* isolates failing echinocandin therapy have been reported (Arendrup et al., 2008).

Treatment of CPA mostly aims at improving quality of life, preventing hemoptysis and disease progression. The lack of proper clinical trials and the difficulty to clearly separate the various subset of CPA impact the ability to offer strong evidence-based recommendations (Denning et al., 2016). Most forms of CPA require long-term medical therapy using either itraconazole or voriconazole. The use of oral triazole therapy depends on the type of CPA, clinical phenotype and eligibility for surgical treatment. Long term oral itraconazole treatment for CCPA is considered the standard of care. First line therapy with dosage are presented in Table 1. Alternative therapy and dosage are available in dedicated guidelines (Denning et al., 2016). Optimal duration of therapy in CPA is unknown, indefinite suppressive therapy may be appropriate in selected patients. Symptomatic hemoptysis therapy may also be part of therapeutic options. Surgery may be considered in single aspergilloma as a definitive treatment option, especially in case of severe hemoptysis. However, to be eligible for surgery a careful selection and assessment of respiratory status of patient is needed as many patients with CPA have comorbidities contributing to a higher death and peri- and post-operative complications.

Treatment of ABPA aims at reducing asthma or CF symptoms, pulmonary inflammation and prevent progression to end-stage fibrotic lung disease. Only oral corticosteroids have proven to improve ABPA symptoms and have been used for decades (Tracy et al., 2016). A recent randomized controlled trial in patients with asthma and ABPA found 0.5 mg/kg/day was effective and safer than higher doses (Agarwal et al., 2016). Duration of treatment is not clearly defined. Although having minimal systemic effects and achieving high concentration in tracheobronchial tree, inhaled corticosteroids have failed to show a benefit in ABPA (Tracy et al., 2016). The adjunction of an antifungal agent to the regimen may have a steroid sparing effect helping control inflammation (Moreira et al., 2014). Triazole such as itraconazole or voriconazole are advised but no consensual approach exists to this date. Anti-IgE (omalizumab) may be a potential immunotherapy, however there is a lack of evidence for the efficacy and safety of this drug in APBA so far (Jat et al., 2018).

Of note, regardless of the aspergillosis subtype, the prescription of triazole antifungal agent requires adjustment with therapeutic drug monitoring (Stott and Hope, 2017). Pharmacokinetics in patients with aspergillosis may vary greatly because of frequent associated comorbidities and drug interactions.

Emergence of resistance and the need for new therapeutic strategy

Azoles are the most important class of antifungal agents used for the management of aspergillosis and include itraconazole, voriconazole, posaconazole and isavuconazole. However, the use of these molecules and successful treatment of aspergillosis have been threatened by emergence of resistance. Triazole resistance has been shown to worsen prognosis in treated patients, demonstrating correlation between microbiological resistance and clinical resistance (Lestrade et al., 2019). Although resistance frequencies vary considerably between geographic regions. While France observes low rate of resistance (Alanio et al., 2016), the prevalence may be up to 10% in the Netherlands and significantly complicates the management of aspergillosis (Verweij et al., 2015). Triazole resistance is largely attributed to mutations of *cyp51A* gene, encoding an enzyme involved in the ergosterol biosynthesis. Two routes are mainly involved in triazole resistance. The first one, known as “the patient route”, occurs mainly in patients with chronic pulmonary aspergillosis or inherited immunodeficiencies who were given azoles for long term course and are the consequence of point mutations in the *cyp51A* (Verweij et al., 2015). The second one, known as “the environmental route”, is usually acquired by azole-naïve patients directly from the environment. The combination of a mutation in the *cyp51A* gene with a tandem repeat (TR) in the promoter region (e.g., TR34/L98H) is usually observed and may cause pan-azole resistance in *A. fumigatus* isolates. Emergence of this resistance mechanism are related to the widely used azole fungicides in agriculture and has been shown to be the most important route for resistance selection (Snelders et al., 2008). In Europe, wood from sawmill, wood chippings, flower bulb waste, green waste materials and soil from marker garden were described as environmental hotspots for triazole resistance selection of *A. fumigatus* (Schoustra et al., 2019). In the light of this upcoming challenge, international expert opinion on the management of infection caused by azole-resistant *Aspergillus fumigatus* were published and depends on the local epidemiology (Verweij et al., 2015). Furthermore, emergence of resistance calls for an urgent need for in depth research and characterization of new therapeutic targets and strategies against this opportunistic pathogen.

Conclusion

The ubiquitous fungal pathogen *Aspergillus* causes a wide spectrum of infections of the respiratory system, which depends heavily on the complex interaction between the host immune system and the pathogen. Collaborations between basic and clinical research on *Aspergillus* and aspergillosis would certainly allow us to overcome the current shortcomings in diagnosis and therapeutic strategies.

Mucorales

Mucorales consist of a group of filamentous molds with aseptate or minimally septate hyphae and evolving taxonomy. The term “mucormycosis” originally belonged to infections caused by agents under two distinct orders, Mucorales and Entomophthorales (Mendoza et al., 2015). Recently scientists prefer to restrict the term to infections caused by Mucorales only, as members of the order Entomophthorales cause chronic subcutaneous infections without any angioinvasion, in contrast to acute course of Mucorales. The epidemiology, pathogenesis, pathology and clinical courses of the diseases caused by fungi under two orders differ considerably (Mendoza et al., 2015; Kwon-chung, 2012). Mucorales inhabit various environmental niches like decaying vegetable matter, soil, dust, etc. They are thermotolerant or thermophilic in nature, a property that imparts contrasting implications. On one hand, they are implicated as rot and spoilage organisms initiating degradation of wet organic material and also fermenting traditional foods and cheese (Reid et al., 2020). On the other hand, their thermotolerant nature enables their growth and survival at human body temperature, thus leading to severe human infection, mucormycosis. Mucormycosis is more prevalent in tropical regions possibly due to the thermotolerance of the agents (Walther et al., 2019b). Being ubiquitously present in nature, Mucorales continue to thrive on various environmental ecosystems, releasing large number of infectious particles as spores. Man acquires the infection by either inhalation/ingestion or inoculation of those spores through the breach of intact skin. In a healthy individual, those spores usually do not get past the host-pathogen interface of effective immune surveillance. However, in patients with compromised immunity or co-morbidities, those spores overcome host defense and grow to produce the disease (Mendoza et al., 2015). In developed countries, severely immunocompromised patients especially with hematological malignancies and transplant recipients are at risk of mucormycosis, but in developing countries uncontrolled diabetes mellitus overshadows other risk factors (Petrikos et al., 2012; Chakrabarti and Singh, 2014). Once the Mucorales get inside the host, the organisms tend to invade the blood vessels. This angioinvasion causes occlusion of blood supply leading to thrombosis, infarction and necrosis of the affected area, and further embolic dissemination leading to substantial morbidity and mortality.

Taxonomy of Mucorales

The taxonomy of Mucorales evolved over the years with expanding knowledge. The earliest taxonomical classification was based solely on morphological characters and sexual reproductive structures. When the sexual structure could be identified, hyphal fungi were placed under *Phycomycetes*, *Ascomycetes*, and *Basidiomycetes* depending on the structure, otherwise they were placed under class *Deuteromycetes* (Fungi imperfecti). The fungi of those four classes were classified under subdivision *Thallophyta* in the plant kingdom (Emmons et al., 1977). Mucorales, owing to coenocytic (aseptate) hyphae and zygosporangia, were categorized under *Phycomycetes*. With the increase in knowledge regarding the habitat, ecology, nutritional requirements and ultrastructure of fungi, a separate kingdom (kingdom Fungi) was proposed by Whittaker in 1969 (Whittaker, 1969). Class *Phycomycetes*, containing the maximum number of evolutionarily unrelated organisms was abolished and four phyla under kingdom Fungi were formed: *Zygomycota*, *Chytridiomycota*, *Ascomycota* and *Basidiomycota* (Kwon-chung, 2012). Phylum *Zygomycota* was further divided into two classes:

Zygomycetes containing mammalian pathogens and *Trichomycetes* containing obligate parasites of arthropods. Order Mucorales was classified under phylum *Zygomycota* and class *Zygomycetes* (along with nine other orders including Entomophthorales) (Kwon-chung, 2012). The spectrum of diseases caused by them were named as “zygomycosis.” The *Zygomycetes* were defined as those coenocytic molds that reproduce sexually with hyphal anastomosis between compatible mating types of the same species having opposite alleles at the mating type locus (Emmons et al., 1977). The mating causes fusion of haploid nucleus with subsequent meiosis and one mitotic division lead to formation of a zygospore. The zygospores are thick-walled, pigmented and often ornamented zygotes. In the presence of appropriate growth conditions, this zygospore germinates to form a sporangiophore (broad aseptate stem-like structure) ending in a sporangium (a spherical receptacle) containing numerous asexual spores, the sporangiospores (Fig. 1). The sporangiospores germinate to form vegetative haploid hyphae (Emmons et al., 1977). The placement of Mucorales under *Zygomycetes* was the accepted classification till the turn of the century.

The advancements in molecular biology enabled genomic relatedness to form the basis of evolutionary relationships. To resolve the lineages under the phylum *Zygomycota*, sequences from more than nine genes were evaluated: three sequences from ribosomal RNA—large subunit, small subunit, 5.8S; two RNA polymerase subunits RPB1 and RPB2; mitochondrial subunit DNA, elongation factor, α - and β -tubulins (Kwon-chung, 2012). The individual analysis of RNA polymerase subunits indicated *Zygomycota* to be monophyletic in origin (Liu et al., 2006). But, all other gene in isolation as well as in combination with RNA polymerase subunits clearly indicated a polyphyletic origin of *Zygomycota*. Consequent to this, a new phylogenetic tree was constructed using small ribosomal subunit. A distinct monophyletic phylum *Glomeromycota* (containing arbuscular mycorrhizal fungi that are plant symbionts) was separated out from *Zygomycota* in 2001 (Schubler et al., 2001). Subsequently, another comprehensive evaluation was carried out in 2007 (Hibbett et al., 2007) on the findings of multiple phylogenetic studies. It was reiterated that *Zygomycota* was polyphyletic and the phylum was divided into four sub-phyla: *Mucoromycotina*, *Entomophthoromycotina*, *Kickxellomycotina*, and *Zoopagomycotina*. However, the placement was left uncertain pending future studies that could better resolve the lineages (Hibbett et al., 2007). Even six-gene phylogenetic tree echoed similar findings, but a reliable outgroup was not identified (Kwon-chung, 2012). Analysis of more than 130 proteins indicated that *Nucleariids* (amoeboids of enigmatic origin) are closely related to Fungi, and could serve as reasonable outgroup (Steenkamp et al., 2006), and the reconstruction of phylogenetic tree using *Nucleariids* as the outgroup led to a separate subkingdom *Dikarya* (containing *Ascomycota* and *Basidiomycota*). However, the previous classification of *Glomeromycota* and four sub-phyla was retained (Liu et al., 2009). With the availability of increasing number of sequences under each taxon, there remains the possibility of further revisions of phylogenetic classification.

In 2016, a phylum-level phylogenetic classification of zygomycete fungi was proposed on the basis of genome-scale data (Spatafora et al., 2016). Genomes of 25 zygomycetes taxa and 192 proteins were combinedly used for phylogenetic analysis. Two clades were defined with paraphyletic relationship, and two phyla were identified under them—*Mucoromycota* and *Zoopagomycota*. Both of these phyla contained three sub-phyla each; Mucorales were placed under phylum *Mucoromycota* and sub-phylum *Mucoromycotina*, while Entomophthorales were placed under phylum *Zoopagomycota* and sub-phylum *Entomophthoromycotina* (Fig. 2) (Spatafora et al., 2016). With this classification, the term “zygomycosis” was abandoned and the terms “mucormycosis” and “entomophthoromycosis” were defined for human infections caused by Mucorales and Entomophthorales, respectively (Kwon-chung, 2012).

Fig. 1 Schematic representation of morphological features of *Rhizopus* spp. showing stem-like sporangiophores arising from branch-like stolons having root-like rhizoids and terminating into sac-like sporangium filled with numerous seed-like sporangiospores. The sub-sporangial structures of apophysis, columella and collarete are also seen.

Fig. 2 Current taxonomical placement of *Mucorales*. Phyla *Mucormycota* and *Zoopagomycota* collectively constitute the “zygomycetes” and human infections are caused by agents under three orders—*Mucorales*, *Entomophthorales* and *Basidiobolales* (seen in bold).

Classification of Mucorales

Based on the phylogenetic analysis, Mucorales currently consist of 261 species under 55 genera (Benny et al., 2016). Human infections have been reported by 38 species under 11 genera—*Actinomucor*, *Apophysomyces*, *Cokeromyces*, *Cunninghamella*, *Lichtheimia*, *Mucor*, *Rhizomucor*, *Rhizopus*, *Saksenaia*, *Syncephalastrum*, and *Thamnostylum*. Members of *Rhizopus*, *Mucor* and *Lichtheimia* are responsible for 70–80% of human mucormycosis cases. Infections with *Apophysomyces*, *Cunninghamella*, *Saksenaia*, *Rhizomucor*, *Cokeromyces*, *Actinomucor* and *Syncephalastrum* spp. are rarely reported (Gomes et al., 2011). The prevalence of species isolated from patients varies geographically, as depicted in Fig. 3.

The medically important genera can be identified on the basis of morphological and physiological characteristics, as shown in Fig. 4.

Rhizopus arrhizus among the members under the genus *Rhizopus* (*R. arrhizus* or *R. oryzae*, *R. microsporus*, *R. homothallicus*) is the most common agent causing mucormycosis globally (Jeong et al., 2019). Genus *Rhizopus* is characterized by unbranched sporangioophores arising singly or in whorls bearing sporangia with apophysis, the rhizoids arising opposite the sporangioophores. The three medically important species are differentiated on the basis of size, shape and ornamentation of sporangiospore. The issue of the correct name of its type species, *R. arrhizus* vs *R. oryzae*, has not been fully resolved. The term *R. arrhizus* was suggested by Fischer et al. (1892) and *R. oryzae* was suggested by Went and Prinsen Geerligs (1895). As *R. arrhizus* had a short description without any figure and type strain, mycologists preferred the term *R. oryzae* for years. However, Ellis (1985) legitimized the name *R. arrhizus* by describing an ex-neotype strain for *R. arrhizus*, which is also clustered phylogenetically with *R. oryzae*.

The genus *Mucor* has 76 accepted species, 12 out of which are pathogenic to man. They commonly cause cutaneous infections or rarely disseminated and gastrointestinal disease. Members of this genera are characterized by formation of sporangia and similar shaped suspensors; the apophysis, sporangiola, and rhizoids are usually absent (Wagner et al., 2019). However, recent studies have shown that certain species under this genera may have rhizoids (Walther et al., 2013).

Genus *Rhizomucor* can withstand high temperature (55°C) and consists of short ellipsoidal sporangiospores. They predominantly cause pulmonary infections. Recently, all mesophilic species of *Rhizomucor* were transferred to *Mucor* on the basis of molecular studies (Walther et al., 2019b).

All thermotolerant members under the genus *Absidia* were separated to form the genus *Lichtheimia*, as they could be differentiated by growth at 43°C and absence of sub-sporangial septum (Garcia-Hermoso et al., 2009; Alastruey-Izquierdo et al., 2010). Members of genus *Lichtheimia* have pyriform sporangia and distinct apophysis over branched sporangioophores. Three pathogenic species, *L. corymbifera*, *L. ramosa* and *L. ornata*, can be differentiated by physiological properties. *L. ramosa* has higher growth rate at 43°C, and *L. ornata* has densely packed giant cells during growth on yeast extract agar (Alastruey-Izquierdo et al., 2010). *Lichtheimia* spp. commonly cause cutaneous and pulmonary infections, and occasionally rhino-orbital form (Alastruey-Izquierdo et al., 2010). *Lichtheimia* spp. are the second most common agents of mucormycosis, after *Rhizopus* spp., in Europe and Africa (constituting 18–24% cases) (Lanternier et al., 2012).

Fig. 3 Inter-continental differences seen in the geographical distribution of agents of mucormycosis.

Fig. 4 A scheme of identification of common agents of mucormycosis on the basis of their morphological and physiological characteristics.

The genus *Apophysomyces* contains six pathogenic species. The organism was first described from the soil of a mango orchard in North India in 1979 (Misra et al., 1979). Subsequently *Apophysomyces* spp. were isolated from soil and decaying matter of the tropical and subtropical regions. The low nitrogen content and alkaline pH of the soil were found to be significantly associated with isolation of *Apophysomyces* species (Prakash et al., 2016). The fungi are more commonly implicated in causing cutaneous mucormycosis especially post-traumatic and post-natural disaster in tropical and sub-tropical regions. *Apophysomyces variabilis* is the second most common agent of mucormycosis in India, after *Rhizopus arrhizus* (Chakrabarti and Singh, 2014; Gomes et al., 2011).

Colonies are brownish grey in color. Sporangiophores are unbranched, arising perpendicularly from aerial hyphae ending in pyriform sporangia with funnel-shaped columella ("Champagne glass" appearance) (Gomes et al., 2011).

There are seven species under genus *Cunninghamella* but only *C. bertholletiae* is pathogenic to humans. It is also a soil fungus found in Mediterranean and subtropical zones. The sporangiophore is straight and branched, ending in globose or pyriform-shaped vesicle from which several sporangia develop. The sporangia are ovoid, single-celled and smooth-walled (Gomes et al., 2011). Mucormycosis due to *Cunninghamella* spp. have highest mortality rates among all Mucorales (Jeong et al., 2019).

The genus *Saksena* is characterized by flask-shaped sporangia with columella and darkly pigmented rhizoids. Three species are recognized to be clinically relevant—*S. vasiformis*, *S. oblongispora* and *S. erythrospora*. The three species can be differentiated by the shape of their sporangiospores—cylindrical in *S. vasiformis*, oblong in *S. oblongispora* and biconcave in *S. erythrospora* (Alvarez et al., 2010). *S. vasiformis* has been associated with cutaneous mucormycosis in tropical and sub-tropical regions (Gomes et al., 2011) and at least 10 case reports of *S. erythrospora* causing cutaneous mucormycosis have been reported (Mukherjee and Kundu, 2018).

The genus *Syncephalastrum* is characterized by cylindrical merosporangium inside which sporangiospores are arranged in rows, giving an *Aspergillus*-like resemblance. *S. racemosum* occasionally produces human infection. The species is usually found in soil and dung, and may be isolated as laboratory contaminant (Gomes et al., 2011). A rare case of rhino-orbito-cerebral mucormycosis due to *Thamnostylum lucknowense* has been reported from India (Xess et al., 2012).

Mucormycosis

Mucormycosis is caused by the fungi under the orders Mucorales and Entomophthorales, and *Mucormycetes*. The diseases caused by Mucorales are different from Entomophthorales, and the fungi under first order produce acute and aggressive disease needing prompt diagnosis and management. The present chapter discusses the diseases caused by Mucorales only.

Magnitude of the problem

Incidence

Mucormycosis has long been considered as a rare disease, however, the incidence has increased manifold in the last two decades (Reid et al., 2020; Ambrosioni et al., 2010). Fig. 5 depicts the density of cases of mucormycosis from different countries across the world. The rise in number of cases has been reported from Belgium (Saegeman et al., 2010), France (Bitar et al., 2009), India (Prakash et al., 2019) Middle East and North Africa (Stemler et al., 2020), Spain (Torres-Narbona et al., 2008; Guinea et al., 2017), Switzerland (Ambrosioni et al., 2010), and United States (Vallabhaneni et al., 2017). A population-based study from France reported a rise in mucormycosis cases from 0.7 per million in 1997 to 1.2 per million in 2006 (Bitar et al., 2009). Belgium reported a eightfold increase in the number of cases per 10,000 patient days over a period of 9 years from 2000 to 2009 (Saegeman et al., 2010). Switzerland reported a sharp rise from 0.57 cases/100,000 population/year to 6.3 cases/100,000 population/year after 2003 (Ambrosioni et al., 2010). The highest burden of mucormycosis is borne by India and Pakistan with 140 cases/million population each, followed by Portugal at 95 cases/million population and Qatar at 12.5 cases/million population (Prakash and Chakrabarti, 2019; Jabeen et al., 2017). The burden of mucormycosis is estimated at four continents having 3 cases/million for North America, 1–3 cases/million for South America and Europe (excluding Portugal) and 0.6 cases/million for Australia (Prakash and Chakrabarti, 2019).

Economic burden

Mucormycosis levies a considerable economic burden as well, much higher than other invasive fungal diseases. The mean treatment cost for mucormycosis in a German healthcare facility was estimated at €53,261 per patient, more than two times that of €28,432 per patient for candidiasis and €21,063 for invasive aspergillosis (Heimann et al., 2018). Further, the patients of mucormycosis required an additional 26.5 days of hospital stay compared to candidiasis or aspergillosis (Heimann et al., 2018). A USA study estimated that there was an additional cost of \$64,526 and length of stay of 16.5 days per patient for invasive mucormycosis (Zilberberg et al., 2014). The cost-of-illness analysis reported the mean daily and overall hospitalization cost per patient of invasive mucormycosis were \$4096 and \$112,419, respectively (Kontoyannis et al., 2016). The main drivers for the high cost of management of mucormycosis were the antifungal drugs and need for specialized critical care units.

Mortality

The all-cause mortality for mucormycosis range from 40% to 80% depending upon the underlying risk factors and the site of mucormycosis (Reid et al., 2020). While healthy non-immunocompromised patients without comorbidities have the highest rate of survival, those with hematological malignancies, stem-cell transplant and extensive burns have the lowest rate of survival. Disseminated forms of the disease, especially those reaching to the central nervous system, generally have mortality rate higher than 80%. Localized sinus disease or limited skin infection have much lower mortality as they are amenable to early diagnosis and surgical resection. Gastrointestinal mucormycosis has also higher mortality due to delay in diagnosis and polymicrobial sepsis ensuing with it (Prakash and Chakrabarti, 2019).

Fig. 5 World map showing the density of cases of mucormycosis across different countries of the world.

Epidemiology

Though the agents of mucormycosis are ubiquitous throughout the world, the epidemiology of mucormycosis varies between the developed and developing countries. This difference is attributed to the difference in risk factors among the patient populations. The important risk factors associated with increased risk of mucormycosis are uncontrolled diabetes mellitus (DM), hematological malignancy (HM) undergoing chemotherapy, hematopoietic stem cell (HSCT) and solid organ transplant (SOT) recipients undergoing immunosuppressive therapy, other immunocompromised hosts (immunosuppression due to HIV, chemotherapy, autoimmune disease therapy), peritoneal dialysis, iron overload, extensive skin injury (burns, trauma) and previous voriconazole therapy (Reid et al., 2020). A cumulative worldwide analysis of 600 publications between 2000 and 2017 revealed that DM was the commonest predisposing factor being present in 40% patients with ketoacidosis in half of the subjects, followed by trauma and HM (32.5% each), solid organ transplant (14%), burns (11%). In 18% patients of mucormycosis, no predisposing factor was identified (Jeong et al., 2019).

On analyzing the risk factors specific to geographical locations, DM was found to be the commonest risk factor in China (Jiang et al., 2016; Chen et al., 2018), India (Chakrabarti et al., 2006; Chakrabarti and Singh, 2014), Iran (Dolatabadi et al., 2018), and Mexico (Corzo-León et al., 2018); while HM and transplant recipients were the major predisposing factors for mucormycosis in Europe and North America (Skiada et al., 2011; Kontoyiannis et al., 2016). Though HM and transplant associated mucormycosis rate have gone up in developing countries as well, DM still overshadows those risk factors (Meis and Chakrabarti, 2009). Globally, the contribution of DM as a predisposing factor for mucormycosis varies from 17% to 88% (Skiada et al., 2011). The prevalence of mucormycosis among Indian diabetics was estimated at 1.6 cases/1000 diabetics (Bhansali et al., 2004). In Iran and Mexico diabetes was reported at 74% and 72% cases of mucormycosis respectively (Corzo-León et al., 2018; Dolatabadi et al., 2018). Though it is claimed that due to the regular use of statins in diabetics, a downward trend of mucormycosis is noted in United States, DM is still a major risk factor (52%) among mucormycosis cases (Kontoyiannis et al., 2016). However, the frequency of DM as risk factor is low (<30%) in European countries, with Italy reporting at 18%, France reporting at 23% and Greece reporting at 29%. The Mucormycosis case registry under European Confederation of Medical Mycology reported DM in 17% of mucormycosis patients (Skiada et al., 2011).

HM is considered the most common predisposing factor for mucormycosis in Europe and the United States, being present in 38% to 62% of the patients (Prakash and Chakrabarti, 2019). Contrary to those high figures, HM was identified as a risk factor for mucormycosis in 13.6% patients in Mexico (Corzo-León et al., 2018), 6.4% patients in India (Prakash et al., 2019) and 3.4% patients in Iran (Dolatabadi et al., 2018). In France 0.4% patients of allogeneic HSCT recipients were reported to develop mucormycosis (Xhaard et al., 2012) while the annual cumulative prevalence of mucormycosis was 0.29% among HSCT patients of the USA (Kontoyiannis et al., 2010).

SOT has been reported as a predisposing factor for mucormycosis in 2–15% cases (Kontoyiannis et al., 2016; Jeong et al., 2019; Prakash et al., 2019). It varies with the type of SOT and the underlying comorbidities. The reported incidences of mucormycosis are 4–16/1000 liver transplants, 13–14/1000 lung transplants, 8/1000 heart transplants and 0.4–0.5/1000 renal transplants (Almyroudis et al., 2006). SOT recipients with additional factors like DM, renal failure, voriconazole prophylaxis and prolonged steroid therapy (>600 mg prednisolone) are at increased risk of developing mucormycosis.

Invasive mould infections in intensive care units (ICUs) are gaining importance in recent years. In a multi-center ICUs study in India, 24% of all invasive fungal diseases were reported to be of mucormycosis (Chakrabarti et al., 2019). The gastrointestinal mucormycosis was seen to occur majorly in premature neonates and adults admitted to the intensive care units (Rammaert et al., 2012).

Mucormycosis has also been reported to occur as breakthrough invasive fungal infection while on antifungal prophylaxis, especially azoles and echinocandins (Lerolle et al., 2014; Fung et al., 2018; Lionakis et al., 2018; Louis-Auguste et al., 2018). In a meta-analysis of 92 breakthrough mucormycosis cases, the patients were either on voriconazole (52%) or fluconazole (25%) or caspofungin (9.8%) (Jeong et al., 2019). Breakthrough mucormycosis had also been reported even when the patient was on Mucorales-active antifungal prophylaxis like posaconazole (Lerolle et al., 2014) or isavuconazole (Fung et al., 2018).

Contrary to the belief that mucormycosis is primarily community-acquired disease, the healthcare-associated mucormycosis is gaining importance. Cases of mucormycosis have been reported from contaminated umbilical catheter, wooden tongue depressors and adhesive bandages and also from hospital air (Richardson and Rautemaa-Richardson, 2020). Mucorales were isolated from both indoor and outdoor environments of a North Indian hospital; with *R. arrhizus*, *Cunninghamella* spp., and *A. variabilis* as common isolates (Prakash et al., 2020). As indicated by the types of exposure, the most common site of involvement was skin (57%) followed by gastrointestinal tract (15%). In a study analyzing 169 cases of healthcare associated mucormycosis over three decades, Rammaert et al. mentioned 69 (41%) cases were at surgical site infections happening commonly after cardiovascular surgery, followed by gastrointestinal, ocular and orthopedic surgery. In 57% cases, the mucormycosis was limited to the skin (Rammaert et al., 2012).

Mucormycosis has also been reported to occur as outbreaks (Antoniadou, 2009). Walther et al. (2019a) have reviewed 32 outbreaks due to Mucorales; 28 occurred in healthcare settings and four in community. The bandages, adhesive tapes, tongue depressor and linen contaminated with Mucorales, were incriminated in the outbreaks of healthcare settings. Among seven outbreaks from contaminated adhesive tapes, five were due to *Rhizopus* spp. and two due to *Lichtheimia* spp. (Patterson et al., 1986; Fréalle et al., 2018). Wooden tongue depressors used as splints for cannulation of neonates or for preparing oral medications were the source of two outbreaks, and *Rhizopus microsporus* was isolated (Walther et al., 2019a). Hospital linen were also implicated in two outbreaks

involving eleven patients infected with *Rhizopus* spp. (Duffy et al., 2014). Contaminated air was the source of nine outbreaks; air conditioners, construction activities and proximity to helipad were indicated as the source, and *Rhizomucor* spp. were isolated in four of those outbreaks (Walther et al., 2019a). In China, 12 cases of intestinal mucormycosis due to *Rhizopus microsporus* were reported over six months in hematology ward. The contaminated corn-starch in allopurinol tablet or ready-to-eat food was considered as the possible source of that outbreak (Cheng et al., 2009). Mucormycosis outbreaks due to *Apophysomyces elegans*, *A. trapeziformis*, and *Lichtheimia* spp. following natural disasters like tsunami, tornado and volcanic eruptions have also been documented (Etienne et al., 2012). An outbreak from contaminated yogurt involving more than 200 consumers occurred in 2013 wherein *Mucor circinelloides* was identified as the causative agent (Lee et al., 2014).

Clinical types

Mucormycosis has varied presentation depending on site of involvement and usually classified as rhino-orbito-cerebral mucormycosis (ROCM), pulmonary, cutaneous, gastrointestinal, and disseminated form. Other less commonly involved sites have been heart, bone, ear, parotid gland, urinary bladder, uterus and lymph nodes (Serris et al., 2019). Isolated renal in immunocompetent host is a unique entity recognized in China and India (Chakrabarti et al., 2001; Yu and Yu Li, 2006; Chakrabarti and Singh, 2014). Fig. 6 depicts the prevalence of each clinical type of mucormycosis and associated major predisposing factors with those types.

ROCM is the most common clinical type of mucormycosis and uncontrolled DM is the most common risk factor (69, 70). Other risk factors identified are SOT, corticosteroid therapy, intravenous drug abuse and renal failure. The patients present with facial swelling, facial pain, nasal ulceration and discharge, epistaxis, sinusitis and cranial nerve palsy in addition to fever and headache. Extension to orbit causes painful eye, blurred vision, proptosis, orbital cellulitis, discoloration and necrosis. Spread to cerebral hemisphere occurs via the superior orbital fissure or the cribriform plate. Massive necrosis can result due to the angio-invasive property of Mucorales. The agents are also notorious for bony erosion and destruction. Cerebral invasion can cause altered mental status, hemiplegia and is associated with high mortality (Lanternier et al., 2012). The overall mortality of ROCM was 41.5%: reaching up to 56% in cerebral involvement, 20% for sino-orbital form and almost nil in disease limited to sinus only (Serris et al., 2019).

Pulmonary mucormycosis, the second most common clinical type of mucormycosis is associated commonly with patients of HM and transplant recipients, though diabetes may also be an associated factor in some cases. HM was identified as the most important risk factor (in nearly 40% patients) by Roden et al. (2005) possibly due to chemotherapy-induced defect in innate pulmonary defenses. In another series including 92 cases of pulmonary mucormycosis, HM was found as risk factor in 32-50% of patients; renal disease in 13-18% cases and transplant in up to 18% cases (9% each in HSCT and SOT) (Feng and Sun, 2018). One study from India reported that 21% cases of pulmonary mucormycosis had history of pulmonary tuberculosis in the past (Prakash et al., 2019). Pulmonary mucormycosis is usually unilateral and upper lobe is the most commonly involved site. The presenting

Fig. 6 Prevalence of different clinical types of mucormycosis and contribution of different predisposing factors for each.

symptoms include high grade fever, cough, pleuritic chest pain, dyspnea and hemoptysis. The 90-day mortality of pulmonary mucormycosis was 48% (Lanternier et al., 2012); and among different species of Mucorales, *Cunninghamella* spp., though rare in frequency, was commonly associated with high mortality (Jeong et al., 2019).

Cutaneous mucormycosis occurs when Mucorales gain entry through the breached skin after trauma or burns. In nearly 44–68% cases, the host is immunocompetent; DM and SOT are reported in few (5–15%) patients only (Skiada et al., 2012). The single most important predisposing factor is penetrating trauma, seen in 25–88% cases followed by contaminated intramuscular injection (42%), open wound injury (21%) (Rodén et al., 2005; Skiada et al., 2012). Other risk factors that predispose to cutaneous mucormycosis are road traffic accidents, surgical procedures, contaminated dressings, burns, natural disasters, animal bites. Cutaneous mucormycosis can be divided into three types on the basis of extent of invasion: (a) localized infection (32–56%) wherein the Mucorales remain restricted to the cutaneous and subcutaneous tissue without further invasion; (b) deep infection (24–52%), wherein deep tissue, muscles, fascia, tendons and even bones may be involved leading to massive necrosis of tissue and blackish eschar; (c) the third type (16–20%) is the one occurring as part of disseminated mucormycosis (Rodén et al., 2005; Feng and Sun, 2018; Skiada et al., 2012). The outcome is better in cutaneous mucormycosis owing primarily to early diagnosis and liberal excision of infected tissue. The 90-day mortality varies between 13 and 23% (Lelievre et al., 2014).

Gastrointestinal mucormycosis (GIM) is rarely reported ante-mortem due to non-specific symptoms or signs and difficulty in collecting samples for diagnosis; majority of the cases are diagnosed accidentally during surgery. The classical risk factors for developing GIM among non-classical immunosuppressed patients were very low birth or premature babies (64%) and malnutrition (17%) in pediatric population; and use of broad-spectrum antimicrobials (27%) diabetes (23%) and dialysis (15%) in adult population (Kaur et al., 2018). Among immunocompromised adults, SOT (52%), neutropenia (38%) and HM (35%) are important predisposing factors (Rodén et al., 2005). The common presenting symptoms are abdominal pain, bleeding and abdominal distension. The most common site of involvement is large intestine followed by stomach and then small intestine. The mortality remains high at 57% owing primarily to delay in diagnosis and management (Dioverti et al., 2015).

Isolated renal mucormycosis (IRM) in apparently healthy individuals is a distinct clinical form with highest number of cases reported from India (Chakrabarti et al., 2001, 2006; Chakrabarti and Singh, 2014) followed by China (Yu and Yu Li, 2006; Lin et al., 2003). Kidney may be involved as part of dissemination in 22% cases of disseminated mucormycosis. Contrary to this observation, in IRM; kidney is the sole organ involved in majority of cases (Chakrabarti and Singh, 2014). In nearly 75% of the Indian cases of IRM, no predisposing factor was identified (Chakrabarti et al., 2001; Chakrabarti et al., 2006). The patients usually present with fever, flank pain, hematuria and anuria. The classical radiological features include enlarged non-hydronephrotic kidneys with hypo-densities, perinephric stranding (Dhaliwal et al., 2015). Over 75% patients are diagnosed ante-mortem due to characteristic clinical presentations and clinical features. However, the disease mortality still remains high (>50%) (Chakrabarti et al., 2001, 2006; Chakrabarti and Singh, 2014). The exact route of acquiring IRM remains unknown and it is speculated that lungs could be a possible source. Though ascending infection could occur, as foci of infection have been documented in both the lungs and urinary bladder in few patients of IRM (Gupta et al., 1998, 2010).

Disseminated mucormycosis is the most severe form and occurs due to the angio-invasive property of the Mucorales. The entity is mostly seen in immunocompromised individuals; SOT and HM serve as the most important predisposing factors. In a meta-analysis of different clinical forms of mucormycosis, disseminated form was found in 13% cases (Skiada et al., 2011). The common site of involvement is lung (>90%) followed by central nervous system (53%). The sinus, liver and kidney involvement may also be part of dissemination. The mortality of disseminated form varies from 58 to 96% (Skiada et al., 2011; Lanternier et al., 2012).

Diagnosis of mucormycosis

The diagnosis of mucormycosis depends on multi-pronged approach involving clinical, radiological, microbiological and histopathological modalities. A high index of clinical suspicion should be kept in mind especially when handling patients with various predisposing factors. Angio-invasion and tissue necrosis are the hallmark of the disease, but waiting for these features to develop may substantially worsen the overall prognosis of the patient. A good clinical judgement, like development of diplopia in a diabetic patient or pleuritic chest pain in a neutropenic patient should alert the clinician of the possible mucormycosis. In premature neonate triad of shock requiring vasoactive drugs, metabolic acidosis, and abdominal distension may alert a neonatologist of possible gastrointestinal mucormycosis (Gupta et al., 2018). Think about mucormycosis in any patient suspected of invasive fungal infection where biomarkers galactomannan or beta-D-glucan are negative. Occasional indolent presentation may cause dilemma in the diagnosis (Celis-Aguilar et al., 2019).

Imaging is one of the earliest modalities ordered to diagnose mucormycosis. Computed tomography may help to delineate the extent of disease in case of ROCM. In case of pulmonary mucormycosis, though the reverse halo sign, multiple nodule are commonly associated with mucormycosis (Chamilos et al., 2005), the patient may present with non-specific infiltrates, pneumonic patches and peripheral ground glass halo (Hammer et al., 2018). The radiological diagnosis is often difficult when the host has coinfection with *Aspergillus* spp. or tuberculosis. Imaging has proven useful in differentiating isolated renal mucormycosis from acute pyelonephritis, glomerulonephritis and renal tuberculosis as enlarged non-functioning kidney with low attenuation areas is suggestive of renal mucormycosis (Chakrabarti and Singh, 2014). 18F-fluorodeoxyglucose (FDG) positron-emission tomography (PET) has also been used to delineate the extent of mucormycosis (Liu et al., 2013).

Microbiological diagnosis involves examination of smear and culture of the offending Mucorales. The most important sample for isolating the agent is the necrotic tissue. Direct microscopic examination of clinical samples with 10% KOH and a fluorescent dye like Calcofluor and Blankophor allow rapid presumptive diagnosis (Cornely et al., 2019; Skiada et al., 2018). The characteristic appearance of Mucorales is described as broad (6–25 µm) ribbon-shaped aseptate or sparsely-septate hyphae with wide-angle branching. The hyphae are friable and hence teasing of tissue should be avoided. Mucorales are non-fastidious in their growth requirements and culture on Sabouraud's dextrose agar usually yield growth in 2–5 days (Ribes et al., 2000). The incorporation of antibacterial agents in SDA would prevent bacterial contamination, but chlorheximide (actidione) should be avoided as it is inhibitory for Mucorales. The fungi have a typical wooly growth and most species sporulate on ordinary media. *Apophysomyces* and *Saksenaea* species, however, do not sporulate easily and may require special media like potato dextrose agar, oat meal agar, cornmeal-glucose-sucrose yeast extract agar, water agar with yeast extract (Chakrabarti et al., 2006). The macroscopic and microscopic examination of the isolate enables identification owing to their distinct morphological features. Once sporulated, the identification, even up to species level, can be made for majority of the Mucorales at the hands of an expert mycologist. Matrix assisted laser desorption ionization time of flight mass spectrometry (MALDI TOF MS) can also be used for species identification in a relatively short span of time by comparing the mass spectra of the isolate with either the in-built database of the machine or in-house database of the individual laboratory (Schwarz et al., 2019). Other commercially-available platforms that can be used for identifying species of Mucorales are ID32C and API 50CH, both from BioMérieux, Marcy l'Etoile, France (Ramani et al., 1998). Once obtained in culture, the Mucorales can be subjected to drug susceptibility testing also, though breakpoints of antifungal drugs are not available for this group of fungi.

As the yield of culture is low (maximum 50%), histopathology is an important tool for diagnosis (Walsh et al., 2012). The most commonly employed stains are hematoxylin and eosin, periodic acid Schiff, and Gomori's methanamine silver wherein the broad aseptate hyphae of Mucorales can easily be visualized (Cornely et al., 2019). The histological feature is the necrosis of the surrounding tissue seen as acute infiltrates involving the blood vessels. The infiltrated blood vessel can be seen having thrombi and infarction. At sites where enough aeration is available, like those involving sinus or a pulmonary cavity communicating with airways, sporulating hyphae can also be seen. The diagnosis of Mucorales on the basis of histopathology is occasionally challenging as characteristic ribbon shaped broad hyphae may not be always present (Kung et al., 2018). For better differentiation, immuno-histochemical stain may be used wherein the specific monoclonal antibody helps differentiate Mucorales from other fungi (Jung et al., 2015).

Molecular assays have greatly revolutionized the identification of the offending Mucorales in culture or in tissue. DNA extraction from paraffin-embedded tissues may pose some difficulty, as paraffin degrades the DNA of the fungi (Millon et al., 2019). Several gene targets have been used for the identification of Mucorales like internal transcribed spacer (ITS), ribosomal targets 18S, 23S, *cytochrome b* and *FTR1* (Millon et al., 2019). Mucorales-specific primers targeting 18S region in semi-nested form are commonly being used for identification of species (Dannaoui, 2009). Other molecular formats with increased sensitivity like real-time PCR followed by high resolution melt curve analysis can also be used (Hrncirova et al., 2010). The sequence so obtained is matched with the available public databases and identification is made on the basis of best match. These molecular assays provide confirmatory identification in cases with overlapping clinical-radiological-histopathological features and help to differentiate Mucorales from *Aspergillus* spp.

Whole genome sequencing and next generation sequencing have been used to identify outbreaks due to Mucorales and define individual properties like those conferring virulence or resistance (Garcia-Hermoso et al., 2018). According to a recent meta-analysis, there has been an increase in the use of molecular diagnosis from 10% in 2005 to 64% in 2017 contributing significantly to our understanding of the epidemiology of Mucorales (Jeong et al., 2019). Though detection of Mucorales specific DNA in body fluid requires standardization, encouraging results have been observed in few studies (Millon et al., 2016; Legrand et al., 2016). The detection of Mucorales specific T-cell may also help in diagnosis (Potenza et al., 2016). Recently, conservation of α 1,6-mannan in Mucorales was exploited to develop a monoclonal antibody (2DA6) based lateral flow immunoassay for diagnosis (Burnham-Marusich et al., 2018). The detection of sesquiterpene, a volatile metabolite in the breath may help in distinguishing mucormycosis from invasive aspergillosis (Acharige et al., 2018). However, all the above molecular or point-of-care tests require standardization before its use in routine laboratory.

Management of mucormycosis

Optimal management requires simultaneous efforts at different fronts—prompt and liberal surgical resection of the necrotic tissue, antifungal administration, correction of immunosuppression and treatment of the underlying disease condition. Untreated cases are universally fatal and a delay in initiation of antifungal therapy by 6 days causes a two-fold increase in mortality (from 48% to 83%) especially in neutropenic patients (Chamilos et al., 2008). An analysis of 929 published cases of mucormycosis revealed that prompt initiation of antifungal therapy and surgical intervention significantly improved survival by 69%, whereas absence of treatment was fatal in 97% (Roden et al., 2005).

Medical management

Among the antifungal agents, lipid formulations (liposomal preparations and lipid complexes) of amphotericin B (AMB), and recently introduced isavuconazole, have been used as the first-line therapy for mucormycosis; while posaconazole or isavuconazole serves as the most effective salvage therapy. Lipid formulations of amphotericin B, have better therapeutic index than conventional

amphotericin B deoxycholate (Gamaletsou et al., 2012). The *in vitro* activity of AMB against Mucorales is quite variable and the optimal dosage for therapeutic use is yet to be determined. Daily dosage ranging from 5 mg/kg/day to 10 mg/kg/day have been recommended (Cornely et al., 2019). However, no significant improvement in outcome was observed by raising the dose to 10 mg/kg/day in the AmBisyo study (Lanternier et al., 2015), rather increased renal toxicity and electrolyte derangements are seen with higher doses (Walsh et al., 2001). Generally 10 mg/kg/day is recommended in central nervous system and bones involvement (Cornely et al., 2019).

Among the triazole antifungal agents, the drugs that act by inhibiting ergosterol synthesis in fungal cell wall, posaconazole and isavuconazole have been found to be effective against Mucorales. The *in-vitro* activity of posaconazole against different species of Mucorales varies with an MIC ranging from 1 µg/mL to 8 µg/mL (Cornely et al., 2017). Posaconazole has been used as salvage therapy in cases refractory to AMB or where AMB therapy is not possible. A response rate of 60% was observed when 91 patients of mucormycosis refractory to AMB were put on salvage therapy using oral suspension of posaconazole (VanBurik et al., 2006). The oral suspension is administered as 800 mg/day in 3–4 doses preferably with high-fat meal or carbonated drinks to increase bioavailability. However, this choice of meal may not be possible for critically-ill patients leading to therapeutic failure (Dolton et al., 2012). To overcome this, delayed release tablet of posaconazole is used that are resistant to gastric acidity and allow steady plasma concentrations with once-daily dosage (Krishna et al., 2012). Intravenous formulation of posaconazole with the addition of β-cyclodextrin has also become available. However, cyclodextrin may increase the chance of nephrotoxicity (Cornely et al., 2017).

Isavuconazole is a broad-spectrum antifungal agent given as prodrug isavuconazonium sulfate. It is recommended as first line therapy for the treatment of mucormycosis in United States, and as salvage therapy both in United States and Europe (Cornely et al., 2019). Both intravenous and oral formulations are available. With linear pharmacokinetics, minimal toxicity and less drug interaction, isavuconazole can be safely given without therapeutic drug monitoring. Though the MIC values of isavuconazole are two- to fourfold higher than those of posaconazole, its excellent bioavailability without any dependence on food makes it a better choice for critically-ill patients (Chitasombat and Kontoyiannis, 2015). One important concern, however, is the reported breakthrough mucormycosis with isavuconazole treatment. Two studies reported breakthrough fungal infection at 18% (Cornely et al., 2015) and 4.6% (Dadwal et al., 2016) while using isavuconazole prophylaxis in leukemia patients. Though therapeutic drug monitoring is not recommended routinely during isavuconazole therapy, long-term administration may require drug level monitoring in patients with sepsis, low or high body weight, hepatic impairment, renal replacement therapy or other extracorporeal devices (Gómez-López, 2020).

The duration of antifungal therapy is not clear and varies according to the response in the patient. The aim is to achieve clinical, radiological and microbiological cure and permanent reversal of immunosuppression. The radiological response is slow in mucormycosis compared to invasive aspergillosis (Legouge et al., 2014). Oral posaconazole or isavuconazole serves as important link to shift the patient from intravenous therapy to oral therapy.

Combination therapy has been used to achieve synergism and broader range especially in immunocompromised patient populations, however, contrasting results have been noticed. While *in vitro* studies showed synergism against Mucorales when combination of AMB and posaconazole was used, *in vivo* murine model showed no benefit (Sipsas et al., 2018; Rodriguez et al., 2008). The synergy of liposomal amphotericin B and echinocandin therapy has been reported both *in-vitro* and *in-vivo* in animal models (Ibrahim et al., 2008; Spellberg et al., 2005). Human studies on combination therapy are limited. In a cohort of 32 patients with HM not responding to first-line AMB monotherapy, favorable response was reported in 56% patients after three months of combination therapy with polyene and posaconazole (Pagano et al., 2013). Currently, the global guideline for management of mucormycosis does not provide discrete recommendation for the use of combination therapy (Cornely et al., 2019). The guideline further highlights the concern on downsides of added toxicity, drug interaction and overall cost (Cornely et al., 2019). Newer agents in antifungal pipeline are few. VT-1161, an inhibitor of fungal CYP51, has good activity against Mucorales and has shown improved survival in neutropenic mice model (Gebremariam et al., 2015). APX001A, inhibiting post-translational protein modification of fungi, has also been tried successfully in mice model (Gebremariam et al., 2017).

Surgical management

Resection of the necrotic tissue in mucormycosis, if possible, improves patient outcome. In cases where the disease is limited, as in cutaneous mucormycosis or ROCM or in localized lesion in any organ, surgical resection can contribute in cure of the disease. In other forms like pulmonary, gastrointestinal and CNS mucormycosis, surgery may be attempted to control further spread of infection (Cornely et al., 2019). Radical or repeated surgeries could control local spread of ROCM in 90% of the patients compared to only 41% patients who has limited surgery (Vironneau et al., 2013). However, a 10-year study on outcome of 44 patients with HM, 13 of whom had mucormycosis, showed no improved outcome with early endoscopic surgery (Davoudi et al., 2015). Even early extensive surgical debridement in immunosuppressed patients, carried a high rate of morbidity and mortality in few studies (Saraiya, 2012; Konigsberg et al., 2020).

Adjunctive therapy

Correction of the underlying risk factor is an important pillar of optimal management of mucormycosis in addition to antifungals and surgical interventions (Sipsas et al., 2018). The neutropenia in patients of HM should be corrected by hematopoietic growth factors and transfusions, administration of corticosteroids should be tapered in patients of autoimmune disorders, anti-retroviral therapy should be started in HIV patients. For patients with uncontrolled diabetes or ketoacidosis, reversal of metabolic acidosis should be corrected by aggressive glycemic control and use of sodium bicarbonate (Cornely et al., 2019). Iron chelators like

deferasirox have been used to scavenge the reduced iron and make it unavailable for Mucorales. Iron is required for fungal growth and its absence helps in inhibiting growth of Mucorales. The beneficial role of iron chelators is best described in patients with ketoacidosis, where continuous acidity causes generation of free iron promoting fungal growth (Cornely et al., 2019). In other patient populations, like those of HM, combination of AMB and iron chelator was counterproductive (Spellberg et al., 2012). Hyperbaric oxygen is occasionally used as adjunctive therapy in cutaneous and rhino-orbital mucormycosis. The hyperbaric oxygen improves the functioning of neutrophils, promotes action of AMB by decreasing acidosis and favors wound healing (Tragiannidis and Groll, 2009). This beneficial effect was noticed more in diabetic patients of mucormycosis than those with HM (John et al., 2005). Augmentation of the immune system has also been tried as useful adjunctive therapy in few case reports. Granulocyte colony stimulating factor, interferon- γ and monoclonal antibody nivolumab that inhibits T-cell apoptosis have been used as rescue therapy in few patients (Gil-lamaignere et al., 2005; Grimaldi et al., 2017). However, all these observations regarding adjunctive therapy require confirmation by randomized clinical trial before recommendation in management of mucormycosis.

Introduction

Fusarium species are filamentous fungi widely encountered in nature, including soil, plants and water biofilms (Kauffmann-Lacroix et al., 2016; LeBlanc et al., 2017), and are important plant pathogens (Raza et al., 2017; Wang et al., 2019). In humans, the most frequent diseases caused by *Fusarium* species are superficial: onychomycosis and keratitis (Homa et al., 2013; Ranawaka et al., 2015). In addition, individuals with severe immunosuppression, particularly patients with acute leukemia and hematopoietic cell transplant (HCT) recipients may develop invasive fusariosis, with typical disseminated skin lesions, positive blood cultures and a frequently fatal outcome (Boutati and Anaissie, 1997). In the text that follows, we will review the characteristics of *Fusarium* spp. and the epidemiology of infection both in immunocompetent and immunocompromised patients. We will also review the clinical presentation, evolution and the management of infection caused by these molds, including treatment and prevention.

Characteristics and taxonomy

Fusarium species (Hypocreales, Ascomycota) are ubiquitous fungi mainly related to disease in plants, causing a great economic concern in agriculture (Daughtrey, 2019). *Fusarium* is also recognized as a human pathogen, with a broad spectrum of clinical manifestations. *Fusarium* is encountered in plants, soil, organic matter, and water biofilms. The disease is acquired both in the community and in the hospital, through direct inoculation or inhalation (Nelson et al., 1994).

More than 300 phylogenetically distinct species have been described, but only a minority is of medical interest (Al-Hatmi et al., 2016; Daughtrey, 2019). Changes in taxonomy are very frequent; tools like GenBank, MycoBank, and Fusarium-ID are excellent sources to keep people updated (Tupaki-Sreepurna and Kindo, 2018). *Fusarium* species are grouped into various phylogenetic species complexes (more than 20), seven of which have been reported to cause significant disease in humans (Table 1): *Fusarium solani* species complex (FSSC), *Fusarium oxysporum* species complex (FOSC), *Fusarium fujikuroi* species complex (FFSC), *Fusarium incarnatum-equiseti* species complex (FIESC), *Fusarium chlamydosporum* species complex (FCSC), *Fusarium dimerum* species complex (FDSC), and *Fusarium sporotrichioides* species complex (FSAMSC) (van Diepeningen et al., 2014). Approximately half of all cases of invasive diseases are caused by FSSC, followed by FOSC (Nucci and Anaissie, 2007). The distribution of species causing disease in humans suffers geographic variations. For instance, while in Brazil and in France FSSC predominates (Herkert et al., 2019; Lortholary et al., 2010), a study evaluating isolates from various European countries found that the most frequent species complex causing human infection was FFSC, especially *F. verticillioides*, and *F. proliferatum* (both belonging to FFSC) (Tortorano et al., 2014).

Clinical spectrum of disease in humans

Fusarium species cause a broad spectrum of infections in humans, including superficial, locally invasive, and disseminated infection (Table 2). The immune status of the host and the portal of entry of infection are the key determinants of the clinical form of fusariosis.

Epidemiology and clinical manifestations of fusariosis in non-immunocompromised patients

The most frequent infections caused by *Fusarium* species in immunocompetent individuals are keratitis and onychomycosis. Other than these infections fusariosis is rare in immunocompetent patients, and occurs usually as a result of skin breakdowns or trauma.

Eye infection

Keratitis was the first clinical disease caused by *Fusarium* species described in humans (Forster and Rebell, 1975). The infection usually develops after trauma, including surgery, or in the presence of other risk factors, such as climate, agricultural work, use of contact lenses and topical corticosteroids (Guarro, 2013). Among the etiologies of corneal ulcer, fungi are responsible for half of the cases, especially *Fusarium* species, being one of the leading causes of blindness in Asian countries (Mahmoudi et al., 2018). The outcome of such infections is usually poor, and many cases of keratitis evolve to endophthalmitis, as show in a recently German case series (Walther et al., 2017).

Outbreaks of keratitis caused by *Fusarium* species have been reported. During 1 year, 164 confirmed cases occurred in 33 US States, with no history of eye trauma. 100 and 54 (94%) patients were users of soft contact lenses; a case-control analysis identified that a specific solution (ReNu with MoistureLock) was related to the outbreak. At least 10 different *Fusarium* species were identified. One-third of the patients required corneal transplantation (Chang et al., 2006). Other outbreaks were subsequently reported, occurring in Singapore and France (Gaujoux et al., 2008; Khor et al., 2006; Saw et al., 2007). In addition to the use of specific contact lens solutions, risk factors for keratitis due to *Fusarium* species include prior topical antibiotics, steroid use for a long time, diabetes and ocular surface problems (Mahmoudi et al., 2018; Mosquera Gordillo et al., 2018).

Fusarium keratitis presents clinically with reduced visual acuity, redness, pain, photophobia and corneal opacity, suggestive of an ulcer (Fig. 1A). The symptoms are milder and more insidious than in keratitis caused by bacteria. The serrated edge finding on ophthalmic examination is frequent (up to 79%), but not pathognomonic. In addition, dry corneal surfaces with feathered margins and satellite lesions have been described (Thomas and Kaliyamurthy, 2013).

Endophthalmitis may occur as a complication of keratitis, and is associated with a poor visual prognosis (Barrios Andres et al., 2018; Dursun et al., 2003). By contrast, endophthalmitis in the immunosuppressed host results from hematogenous seeding, in the setting of disseminated infection (Rizzello et al., 2018).

Superficial skin infection

While the large majority of cases of onychomycosis are caused by dermatophytes, non-dermatophyte molds, including *Fusarium* species, have been increasingly reported as causes of onychomycosis (Gupta et al., 2003; Ng et al., 1999; Ramani et al., 1993; Ranawaka et al., 2012). The typical clinical presentation is that of distal subungual lesion in the toe nails, occurring more frequently in females (Fig. 1B) (Calado et al., 2006; Ranawaka et al., 2015). In addition to onychomycosis, *Fusarium* species may occasionally cause interdigital intertrigo (Fig. 1C), tinea pedis and hyperkeratotic plantar lesions (Calado et al., 2006; Hay, 2007). In severely immunocompromised patients, onychomycosis or intertrigo caused by *Fusarium* species may serve as portal of entry for cellulitis with or without disseminated infection (Nucci et al., 2013b).

Other infections

In addition to superficial skin infections, patients who suffer deep trauma, burns, or have predisposing conditions such as diabetes mellitus, may develop cellulitis and soft tissue infection, with necrosis, abscess formation, plaques, ulcers, nodules and eumycetomas, characterized by tumefaction, draining secretions with grains (Al-Hatmi et al., 2017; Dutta et al., 2013; Muhammed et al., 2013; Nucci and Anaissie, 2002). In addition, there are a few reports of infection in non-immunocompromised patients, including peritonitis in patients receiving continuous ambulatory peritoneal dialysis (Gaur et al., 2010), septic arthritis (Jakle et al., 1983), pneumonia (Nucci et al., 2015), sinusitis (Gamba and Lombardi, 2017; Hashemi et al., 2015; Lee et al., 2012), thrombophlebitis (Murray et al., 2003), and osteomyelitis (Schade and England, 2019). Sinusitis in immunocompetent individuals may manifest as allergic and chronic non-invasive disease (Wickern, 1993). An allergic form of pneumonia has also been described in immunocompetent patients (Backman et al., 1995).

Epidemiology of fusariosis in immunocompromised patients

Invasive fusariosis occurs predominantly in patients with acute leukemia and in HCT recipients. A prospective study conducted in eight Hematology centers in Brazil evaluated 237 patients with acute myeloid leukemia (AML) or myelodysplasia (MDS) receiving intensive induction chemotherapy and 700 HCT recipients (378 allogeneic and 322 autologous). The overall 1-year cumulative incidence of invasive fungal disease (IFD) was 18.7%, 11.3% and 1.9% in AML/MDS, allogeneic and autologous HCT, respectively. Invasive fusariosis (23 episodes) was the most frequent IFD. The incidence of fusariosis was 5.2% in AML/MDS, 3.8% in allogeneic HCT, and 0.6% in autologous HCT. The 6-week probability of survival of patients with invasive fusariosis was 41% (Nucci et al., 2013a).

In a previous study describing the epidemiology of invasive fusariosis in HCT recipients, the overall incidence was ~6 cases per 1000 HCT, being lowest in autologous (1.5-2/1000 HCT), intermediate in HLA matched donor allogeneic HCT (2.5-5/1000) and highest (20/1000 HCT) in mismatched related donor HCT, with a trimodal distribution: the first peak in the pre-engraftment

Fig. 1 Clinical manifestations of fusariosis in immunocompetent and immunocompromised patients. (A) Redness and corneal opacity of *Fusarium* keratitis, (B) distal subungueal lesion in the toe nails of *Fusarium* onychomycosis, (C) interdigital intertrigo caused by *Fusarium* species, (D) disseminated skin lesions of invasive fusariosis, (E) Pneumonia caused by *Fusarium* species, (F) Paranasal cellulitis of *Fusarium* sinusitis..

period, the second occurring ~day + 70, in the context of acute graft versus host disease (GVHD), and the third occurring >1 year, in the context of chronic GVHD (Nucci et al., 2004).

A study evaluated risk factors for invasive fusariosis in hematologic patients. Among patients with AML/MDS, active smoking was the only significant variable. In allogeneic HCT, receipt of antithymocyte globulin, hyperglycemia and AML were risk factors in the pre-engraftment period, and non-myeloablative conditioning regimen, grade III-IV GVHD and previous invasive mold disease were risk factors in the post-engraftment period (Garnica et al., 2015).

Immunocompromised patients may be exposed to *Fusarium* species both in the community and in the hospital. In 2007 we observed an increase in the incidence of invasive fusariosis with a cutaneous portal of entry (onychomycosis and interdigital

intertrigo), and suspected that the patients might have been admitted with skin lesions that became colonized and subsequently infected by *Fusarium* in the hospital, since *Fusarium* had been recovered from the hospital water system (Nucci et al., 2013b). However, cases of invasive fusariosis were caused by FSSC whereas most environmental isolates were FOSC, and among concordant species, most did not exhibit genotypic similarities (Scheel et al., 2013). Furthermore, in the same period we observed an increase in the recovery of *Fusarium* species from skin lesions of immunocompetent patients from the Dermatology outpatient unit (Nucci et al., 2013b). Taken together, these data indicated a community origin of invasive fusariosis. On the other hand, cases of invasive fusariosis associated with a hospital source of infection have been reported both from the air (Moretti et al., 2018) and from the hospital water system (Anaissie et al., 2001).

Invasive fusariosis has been occasionally reported in solid organ transplant recipients, but the frequency is much lower than in patients with hematologic malignancies and HCT recipients (Carneiro et al., 2011).

Clinical manifestations of invasive fusariosis in immunocompromised patients

The top four clinical presentations (Table 3)

Invasive fusariosis in severely immunocompromised patients manifests in four major clinical presentations: fever and disseminated skin lesions, pneumonia, fever and positive blood culture for a mold, and superficial infection in the feet with subsequent lymphangitis.

The most frequent clinical presentation is that of disseminated disease. This form is particularly frequent in patients with severe neutropenia, and starts with the sudden appearance of one or (more frequently) various skin lesions (see detailed description below) in the context of persistent or recurrent fever (Boutati and Anaissie, 1997). This picture is usually accompanied by generalized myalgia, and a toxemic appearance.

Skin involvement

In a review of skin lesions in 167 immunocompromised patients, we found localized lesions in 20 patients only. Among 147 patients with disseminated disease, the most frequent skin lesions were multiple painful erythematous popular or nodular lesions, with or without central necrosis, with an ecthyma gangrenosum-like appearance (Fig. 1D). The lesions involved all parts of the body, with predominance to the extremities, and evolved over a few days. Myalgia was a frequent symptom (Nucci and Anaissie, 2002).

The evolution of the skin lesions in cases of disseminated fusariosis is important to assess treatment response. Once the treatment is started, nodular lesions begin to flatten, reduce in size and no new lesions appear. On the other hand, the continuous appearance of new skin lesions in a patient under treatment is a clear sign of therapeutic failure.

A cutaneous portal of entry of fusariosis may occur. In a series of 21 cases of invasive fusariosis occurring in our hospital between 2000 and 2010, 14 (66.7%) had a cutaneous portal of entry: onychomycosis with periungueal cellulitis in six, onychomycosis with interdigital intertrigo in one, intertrigo with lymphangitis in two, interdigital intertrigo in four, and ulcer in one case (Nucci et al., 2013b). Patients with skin portal of entry may evolve to localized skin infection only, or (more frequently), subsequently present with disseminated disease.

Pneumonia

Pneumonia is a frequent manifestation of fusariosis in immunocompromised patients, occurring in 145 of 317 (46%) patients (Fig. 1E), with 73% of patients presenting with bilateral lung involvement (Nucci et al., 2015). The pathogenesis of fusarial pneumonia in immunocompromised patients is similar to aspergillosis, with a first bronchoalveolar phase, followed by angioinvasion (in neutropenic patients) and lung infarction. We have compared the clinical characteristics of 26 cases of invasive fusariosis with 36 cases of invasive aspergillosis occurring in hematologic patients (Nucci et al., 2018). Pneumonia occurred in 88.9% and 50% of cases of aspergillosis and fusariosis, respectively. The most frequent radiologic lesions in fusariosis were macro (>1 cm) nodules (61.5%), centrilobular micro (<1 cm) nodules and ground-glass infiltrates (53.8% each). The only significant difference between aspergillosis and fusariosis lung infection was that macronodules with halo sign were more frequent in cases of

Table 3 Clinical presentations of invasive fusariosis in immunocompromised patients.

Clinical presentation	Characteristic	Comments
Fever + skin lesions	Persistent or recurrent fever in neutropenic patients + sudden onset of nodules and papules	Most frequent clinical presentation of disseminated disease
Pneumonia	New images in chest CT scan	Nodules with or without halo sign, alveolar consolidations, tree in bud, ground-grass infiltrates
Fever + positive blood culture for a mold	Persistent or recurrent fever in neutropenic patients + positive blood culture for a mold	Most frequent mold recovered in blood cultures in neutropenic patients
Superficial skin lesions with subsequent lymphangitis	Onychomycosis or interdigital intertrigo on admission with sudden appearance of lymphangitis	Primary skin lesions frequently overlooked in routine physical examination

CT, computed tomography.

aspergillosis (62.5% vs. 23.1%, $P = .02$). Another important finding in this study was that in 31% of patients with fusariosis and lung involvement, the disease presented with pneumonia as the sole manifestation. Considering that patients with invasive fusariosis may have positive galactomannan test (Nucci et al., 2014a), the distinction between fusariosis and aspergillosis may be difficult.

An important difference between fusariosis and aspergillosis is that while in aspergillosis the disease is acquired by inhalation of conidia, in fusariosis pneumonia may occur either by inhalation of conidia or by hematogenous route from a primary skin lesion. Interestingly, compared with patients with an airborne acquisition, those with a cutaneous portal of entry are more likely to have bilateral lung involvement (Nucci et al., 2015).

Sinusitis

Sinusitis has been reported in patients with invasive fusariosis. In a literature review, 52 of 262 immunocompromised patients (20%) had sinusitis (Nucci and Anaissie, 2006). In our comparison between cases of aspergillosis and fusariosis occurring in patients with hematologic diseases, sinusitis was diagnosed more frequently in aspergillosis (63.9% vs. 38.5%, $P = .048$) (Nucci et al., 2018). The clinical manifestations of fusarial sinusitis may vary from slight headache and nasal discharge to mucosal necrosis and periorbital and paranasal cellulitis (Fig. 1F).

Fungemia

The growth of molds from blood cultures is not frequent. A few organisms produce yeast-like structures, called aleuroconidia, that invade the bloodstream causing fungemia (Nucci and Anaissie, 2007). The most frequent mold causing bloodstream infection is *Fusarium* species. In a series of 233 cases of invasive fusariosis in hematologic patients, fungemia occurred in 37% of cases (Nucci et al., 2014b). Occasionally fungemia is the sole manifestation of invasive fusariosis, sometimes in the absence of neutropenia, in the context of catheter-related infection. This form of invasive fusariosis is usually associated with good prognosis (Carlesse et al., 2017; Velasco et al., 1995).

Disseminated infection

Disseminated infection is the most frequent clinical presentation of invasive fusariosis in immunocompromised patients. Typically the patient presents with disseminated skin lesions, fungemia and pneumonia (Nucci and Anaissie, 2007). This form of invasive fusariosis is more likely to occur in severely neutropenic patients, and is associated with poor outcome (Nucci et al., 2014b). Occasionally patients develop endophthalmitis in the context of disseminated disease that may complicate with blindness (Tiribelli et al., 2002).

Diagnosis of fusariosis

The diagnosis of fusariosis depends on the clinical form. Superficial infections caused by *Fusarium* species usually do not have typical clinical manifestations that per se suggest or indicate the diagnosis of fusariosis. By contrast, in severely immunocompromised patients, two clinical presentations are highly suggestive of invasive fusariosis: positive blood culture for a mold, and the appearance of multiple skin lesions.

Apart from clinical presentation, the diagnosis of fusariosis (as occur with other fungi) relies on direct exam, culture and histopathology. In addition, antigen detection and molecular diagnostic tests may be of help.

The diagnosis of fusariosis is based on the identification of the fungus in culture. The specimen to be examined depends on the clinical presentation, and is mostly represented by the skin, nails, cornea, blood, bronchoalveolar lavage and sinus drainage (Fig. 2) (Nucci and Anaissie, 2002). A special attention is needed in the interpretation of culture from non-sterile specimens, since environmental contamination may occur. With this regard, a direct exam of the biologic material showing acute-branching septate hyaline hyphae is of great help to interpret a positive culture as indicating infection and not contamination.

In culture, *Fusarium* species grow easily and rapidly in most media without cycloheximide. On dextrose potato agar, colonies have a velvety or cotton surface and have different colors (white, yellow, pink, purple, or gray salmon) (Nelson et al., 1994). Although the genus *Fusarium* can be identified by the production of hyaline, banana-shaped, multicellular macroconidia with a foot cell at the base, species identification is difficult and requires molecular methods. In tissue, the hyphae are septate, hyaline with dichotomization at an acute angle, a common characteristic of the agents of hyalophycomycoses and of *Aspergillus* species. However, adventitious sporulation that is characteristic of *Fusarium* may be present in tissue, and the finding of hyphae and yeast-like structures together is highly suggestive of fusariosis in the high-risk population.

A study evaluated the performance of a specific fungal medium and a standard aerobic medium of Bactec™, and found that fungal medium should be preferably used in patients with suspected invasive fusariosis (Hennequin et al., 2002). In another study, bacteria and molds (including *Fusarium*) are inoculated in the same blood culture bottles of Bactec™. Bottles with selective fungal media had a better performance than aerobic media (Oz et al., 2020). In the experience of the authors with BacTAlert™ aerobic bottles, the median time to positivity of blood cultures was 3 days (range 1–4) (Nucci et al., 2014a).

As stated before, the identification of *Fusarium* at species level requires molecular techniques. Two different regions have been used for DNA amplification: the internal transcribed spacer (ITS) and the elongation factor 1 alpha (EF-1alpha), with primers with high specificity (Boch et al., 2016; de Souza et al., 2017; Wehrle-Wieland et al., 2018). Unfortunately, this technique is expensive, required better extraction protocols, and is not available in most laboratories. More recently, matrix-assisted laser desorption/

Fig. 2 Tools often required for specimen collection to fusariosis diagnosis. (A) Corneal scraping for the diagnosis of *Fusarium* keratitis, (B) nail scraping for the diagnosis of *Fusarium* onychomycosis, (C) bronchoscopy with bronchoalveolar lavage for the diagnosis of *Fusarium* pneumonia, (D) blood cultures are frequently positive in invasive fusariosis, (E) skin biopsy with culture and histopathology for the diagnosis of disseminated fusariosis.

ionization flight time (MALDI-TOF) has been evaluated in species identification, both in pure colonies and directly from bottles of positive blood cultures (De Carolis et al., 2012; Walsh and McCarthy, 2019).

In addition to conventional mycology, another approach to establish the diagnosis of invasive fusariosis is the use of fungal biomarkers. The two main targets are polysaccharides present in the fungal cell wall: galactomannan (GMI) and 1,3- β -D-glucan (BDG). While GMI is a backbone in the diagnosis of invasive aspergillosis and initially was thought to be specific for *Aspergillus*, cross reactivity may occur with some fungi, including *Fusarium* (Boch et al., 2016; Tortorano et al., 2012). In a multicenter study, we found that 15 of 18 patients (73%) with invasive fusariosis had at least one positive serum GMI test. The test was positive before the

diagnosis of invasive fusariosis in 11 of the 15 cases (73%), at a median of 10 days (range 3–39) (Nucci et al., 2014a). In another study, we compared the characteristics of 36 hematologic patients with invasive aspergillosis and 26 with invasive fusariosis. Serum galactomannan was positive in 88.6% of patients with aspergillosis and in 73.3% with fusariosis (Nucci et al., 2018). While there are important differences in the clinical presentation of aspergillosis and fusariosis, such as skin lesions and positive blood cultures, which are much more frequent in fusariosis, in our study, positive serum galactomannan plus lung infiltrates was the clinical presentation of 4 of 13 patients with invasive fusariosis who had pneumonia. In these cases, it is difficult to differentiate between fusariosis and aspergillosis.

Unlike GMI, which is considered a reasonably specific fungal biomarker for *Aspergillus*, BDG is a component of various fungi, including *Candida*, *Aspergillus* and *Fusarium* (Odabasi et al., 2004). We tested serum samples of 13 patients with invasive fusariosis, analyzing the temporal relationship between the first positive BDG test and the date of the diagnosis of fusariosis, and evaluated the performance of the test in the diagnosis of fusariosis. Twelve of the 13 patients had at least one positive serum BDG test, and it was positive before the diagnosis of fusariosis in 11 of the 12 patients (91.6%), at a median of 10 days (range 1–32). However, as BDG is associated with various false positive tests (Mikulska et al., 2015), the positive predictive value was very low (7%, considering two consecutive positive BDG tests). Therefore, serum BDG is more useful at ruling out rather than confirming the diagnosis of invasive fusariosis.

Management

The treatment of invasive fusariosis varies according to the immune status of the host and the site(s) of infection. The treatment of the two most frequent infections occurring in immunocompetent individuals, keratitis and onychomycosis, is challenging. By contrast, the sporadic cases of localized infection in immunocompetent individuals can be treated with surgical debridement. On the other hand, infection in immunocompromised patients requires systemic therapy, and the main determinant of the outcome is the immune status of the host.

Treatment of fusariosis in immunocompetent patients

Keratitis

The treatment of keratitis caused by *Fusarium* species is challenging because of the poor tissue penetration of antifungal agents. The treatment usually consists of using a topical antifungal agent alone, or in combination with systemic therapy. Natamycin, a polyene amphoteric molecule, has been used for more than 50 years and continues to be the first line treatment (Ansari et al., 2013). In a non-randomized, comparative prospective study in patients with fungal keratitis, patients treated with natamycin 5% eye drops hourly showed better success outcomes than patients receiving topical itraconazole 1% eye drops (Kalavathy et al., 2005). A randomized study compared topical 5% natamycin with 1% voriconazole. The proportion of patients with healed or resolved ulcer was significantly higher in natamycin recipients (89.2% vs. 66.6%) (Sharma et al., 2015). Another randomized controlled trial comparing natamycin with voriconazole showed a benefit of topical natamycin over topical voriconazole, while adding oral voriconazole resulted in a trend towards a decreased rate of ulcer perforation (Prajna et al., 2016, 2017). Topical amphotericin B is an option if natamycin is not available. Surgical intervention is reserved for patients with refractory disease. While corneal scraping should be limited to obtaining diagnostic samples, the most common therapeutic surgery is penetrating keratoplasty, followed by lamellar keratoplasty (Ansari et al., 2013).

Onychomycosis

The management of onychomycosis caused by *Fusarium* species is challenging, with a long duration of treatment, and high failure rates with both systemic and topical therapy. For topical treatment, amphotericin B solution (2 mg/mL) is the preferred agent (Monod and Mehul, 2019). Laser therapy may occasionally work (Khurana et al., 2018), as well as a combination of topical and oral terbinafine (Shah et al., 2016). Among systemic therapies, terbinafine and itraconazole have been used more frequently, with variable response rates (Hattori et al., 2005; Ranawaka et al., 2008, 2015). In hematologic patients who present with onychomycosis or interdigital intertrigo before receiving chemotherapy or transplant, systemic voriconazole or posaconazole reduce the risk of dissemination during periods of severe immunosuppression (Varon et al., 2014, 2016).

Management of fusariosis in immunocompromised patients (Table 4)

Prognostic factors

In neutropenic patients, neutrophil recovery is the most important prognostic factor in invasive fusariosis. In addition, T-cell immunodeficiency associated with the use of corticosteroids impacts the outcome. In an analysis of 84 hematologic patients with invasive fusariosis, the 90-day survival was 21%. By multivariate analysis, factors associated with death were persistent neutropenia (hazard ratio 5.43) and receipt of corticosteroids (hazard ratio 2.18). The actuarial survival was 0% for patients with persistent neutropenia and on corticosteroids, 4% for those with persistent neutropenia only, 30% in patients on corticosteroids but no neutropenia, and 67% in patients without any of these two factors (Nucci et al., 2003). In another study analyzing the outcome of 206 patients with invasive fusariosis who received treatment, variables associated with death were receipt of corticosteroids (hazard

Table 4 Recommendations for the management of invasive fusariosis in severely immunosuppressed patients.

Action	Drug	Comments
Primary prophylaxis	Voriconazole or posaconazole	High-risk hematologic patients who present on admission with superficial skin lesions with positive cultures for <i>Fusarium</i> spp.
Secondary prophylaxis	Voriconazole, posaconazole or lipid amphotericin B	Patients with prior invasive fusariosis who will be exposed to subsequent periods of immunosuppression
Primary therapy	Lipid amphotericin B or voriconazole or combination therapy	Outcome largely dependent on recovery of host defenses

ratio 2.11), persistent neutropenia (hazard ratio 2.70), and receipt of deoxycholate amphotericin B (hazard ratio 1.83) (Nucci et al., 2014b).

In vitro susceptibility

Fusarium species exhibit high minimal inhibitory concentrations (MICs) to most antifungal agents including the voriconazole, posaconazole, isavuconazole and amphotericin B. Epidemiologic cutoff values of different antifungal agents tested in 1150 *Fusarium* isolates belonging to different species complexes (Espinel-Ingroff et al., 2016). For FSSC (608 isolates tested), MIC ranges and mode ($\mu\text{g/mL}$) were ≤ 0.25 –16 and 2 for amphotericin B, 0.5 — >16 and 16 for itraconazole, 0.5 — >16 and 8 for voriconazole, and 1 — >16 and 8 for posaconazole. For FOSC, MIC ranges and mode ($\mu\text{g/mL}$) were ≤ 0.25 –16 and 2 for amphotericin B, 1 — >16 and 16 for itraconazole, 0.5 — >16 and 4 for voriconazole, and 0.5 — >16 and 2 for posaconazole. Preliminary data on the in vitro activity of isavuconazole also indicate poor activity. A study evaluating 75 isolates of *Fusarium* of different species complexes showed a MIC₅₀ of >16 $\mu\text{g/mL}$, without great variations between species (Broutin et al., 2020).

A very important clinical question regarding MICs for *Fusarium* species is whether results of in vitro susceptibility tests are of help to select the appropriate treatment. Indirect clinical experience suggests that this might not be the case, as shown by the good clinical response to voriconazole in patients with invasive fusariosis, with rates similar to those achieved by lipid amphotericin B, despite the high MICs exhibited in the susceptibility test studies (Lortholary et al., 2010; Nucci et al., 2014b). More recently, a multicenter study analyzed the correlation between MIC and the outcome in 88 cases of fusariosis, 74 with hematologic diseases. There was no difference in MIC₅₀ and MIC distribution among survivors and patients who died. By contrast, persistent neutropenia and receipt of corticosteroids were strong predictors of 6-week mortality (Nucci et al., 2020).

Primary prophylaxis

Primary anti-mold azole prophylaxis (posaconazole or voriconazole) is considered standard of care in high-risk hematologic patients, including patients with AML receiving intensive chemotherapy as remission induction and allogeneic HCT (Maertens et al., 2018). In this scenario, breakthrough infection by *Fusarium* species have been reported (Cudillo et al., 2005; Wu et al., 2014). Primary prophylaxis for invasive fusariosis was evaluated in one study, in a subset of patients. We reported an increased incidence of invasive fusariosis with a cutaneous portal of entry, with most patients presenting onychomycosis and interdigital intertrigo (Nucci et al., 2013b). Subsequently, we conducted a prospective study to evaluate the frequency of such lesions in hematologic patients, and observed that patients with superficial skin lesions in the feet (interdigital intertrigo and/or onychomycosis) on hospital admission with positive culture for *Fusarium* spp. were at an increased risk to develop invasive fusariosis (Varon et al., 2014). Then, in a non-randomized trial, we administered anti-mold prophylaxis (voriconazole or posaconazole) in 20 episodes at risk (neutropenia or graft versus host disease), and compared with 219 episodes where fluconazole or no prophylaxis was given. Invasive fusariosis occurred in 5.9% without and in 5% with anti-mold prophylaxis. However, 4 of 5 patients with superficial skin lesions with positive cultures for *Fusarium* species who did not received anti-mold prophylaxis developed invasive fusariosis vs. none of ($P = .01$) (Varon et al., 2016). On the basis of these data, we recommend primary prophylaxis with an anti-mold azole (voriconazole or posaconazole) in high-risk hematologic patients who present on admission with superficial skin lesions with positive cultures for *Fusarium* spp.

Secondary prophylaxis

Secondary prophylaxis refers to the use of an antifungal agent to patients with prior story of invasive fusariosis who will be submitted to subsequent periods of immunosuppression. Secondary prophylaxis was evaluated in a multicenter retrospective study of 40 patients who were successfully treated for invasive fusariosis and were exposed to subsequent periods of immunosuppression (neutropenia in 35 and graft versus host disease in 5). Relapse of invasive fusariosis occurred in 2 of 8 patients (25%) who were not on prophylaxis and in 3 of 32 (9.4%) who received secondary prophylaxis (voriconazole in 24, posaconazole in 2 and a lipid formulation of amphotericin B in 6). Considering only patients who had disseminated fusariosis, relapse occurred in 2 of 2 (100%) not on secondary prophylaxis and in 3 of 26 (11.5%) who received secondary prophylaxis ($P = .03$) (Nucci et al., 2019). Therefore, secondary prophylaxis with a mold-active azole or a lipid formulation of amphotericin B should be strongly considered in patients

with prior invasive fusariosis who will be exposed to subsequent periods of immunosuppression, especially if the disease was disseminated.

Other preventive measures

Other preventive measures in immunocompromised patients at high risk to develop invasive fusariosis include preventing patients' exposure by treating these patients in rooms with HEPA filter and positive pressure and avoiding contact with reservoirs of *Fusarium* (Anaissie et al., 2001). In addition, decreasing immunosuppression (if possible) should be attempted in patients with prior invasive fusariosis (e.g., use of colony-stimulating factors in patients who will become neutropenic).

Primary therapy

It is difficult to define the best regimen for the treatment of invasive fusariosis because there are no randomized trials and because the outcome is largely dependent on immune reconstitution. The largest series ever published is a multicenter retrospective study of 236 patients diagnosed between 1985 and 2011 in 44 centers from 11 countries. Among 206 patients who received treatment, deoxycholate amphotericin B was given to 110 patients, 38 received voriconazole, 34 were treated with a lipid formulation of amphotericin B (liposomal 20, lipid complex 8, colloidal dispersion 6), 21 received combination therapy (mainly voriconazole plus amphotericin B), and 3 received other therapies. The 90-day probability of survival was 53% for patients receiving voriconazole, 48% for those receiving a lipid formulation of amphotericin B, and 27% for patients treated with deoxycholate amphotericin B. The response rate was similar among patients receiving combination therapy and monotherapy (Nucci et al., 2014b).

Posaconazole and isavuconazole have some in vitro activity against *Fusarium* species, but the experience with these agents in the primary treatment of invasive fusariosis is very scarce. For example, among 206 patients with fusariosis treated in 44 centers worldwide, only two patients were treated with posaconazole (Nucci et al., 2014b).

Many clinicians start treatment with a combination of voriconazole and a lipid formulation of amphotericin B, with the argument that the disease is very severe, with a poor outcome, and because MICs for voriconazole are high. However, there are no data indicating that combination therapy is better than monotherapy. Furthermore, the similar response rates in patients receiving monotherapy with voriconazole or a lipid formulation of amphotericin B are against in vitro data that shows higher MICs for voriconazole. These data suggest that results of in vitro susceptibility tests are of little help in establishing the optimal treatment for invasive fusariosis.

Assessment of treatment response

As stated above, the outcome of invasive fusariosis is largely dependent on immune reconstitution. In patients with metastatic skin lesions, daily examination and counting of lesions is very helpful to assess treatment response. Responding patients should not present new skin lesions, and the existing lesions should flatten. In addition, myalgia, which is very frequent, should improve, and blood cultures should become negative. In patients with isolated lung involvement the assessment of treatment response is more complicated because as in aspergillosis (Caillot et al., 2001), lesions can increase in size after the first week of treatment.

Salvage therapy

In practice, changes in the primary therapy usually include either switch from one drug to another (from voriconazole to lipid amphotericin B or vice versa) or to give combination therapy. However, we have to keep in mind that patients who fail to respond to treatment and have persistent neutropenia are very unlikely to respond to any treatment regimen.

Adjunctive therapies

Adjunctive therapies include removal of central venous catheters in the occasional cases of catheter-related fungemia (Velasco et al., 1995), the use of granulocyte or granulocyte-monocyte colony-stimulating factors (G-CSF and GM-CSF), interferon gamma and granulocyte transfusions to persistently neutropenic patients. While many patients receive these adjunctive therapies, their effectiveness have not been proven.

A single center study reported 11 patients with invasive fusariosis who received granulocyte transfusions as adjunctive therapy. With a median of 7 transfusions per patient, neutrophil counts remained $>500/\text{mm}^3$ for 36 h in 61% of transfusion events. Clinical response was observed in 10 of the 11 patients, and 8 patients were alive 3 months after the diagnosis of fusariosis. In the same article, a literature review of 23 published cases showed a response rate of 30% only (Kadri et al., 2015).

Conclusions

Infections by *Fusarium* species may occur in immunocompetent and in immunocompromised patients. Onychomycosis and keratitis are the most frequent infections in humans. Other than these two infections, immunocompetent patients may occasionally develop deep-seated infection that is limited to single organs, and tend to respond well to therapy. By contrast, immunocompromised patients, especially HCT recipients and patients with severe and prolonged neutropenia, frequently develop disseminated disease, which is frequently fatal. In such patients, successful outcome is largely determined by the degree and persistence of immunosuppression and the extent of infection.

Introduction

Implantation mycoses include a diverse group of fungal diseases with subacute to chronic manifestations that start at the site of transcutaneous trauma. These diseases are also known as “subcutaneous mycoses,” but this term is inadequate, as involvement may go beyond the skin and subcutaneous tissues to involve deeper structures like the lymphatic vessels, osteoarticular system, and bones (Arenas, 2005; Errol Reiss et al., 2012; Queiroz-Telles et al., 2011).

Sporotrichosis is the most prevalent and globally distributed of the implantation mycoses (Chakrabarti et al., 2015a; Queiroz-Telles et al., 2017). It is caused by several *Sporothrix* species, a genus of thermally dimorphic fungi that infect humans and animals. This disease usually develops after inoculation with contaminated organic material or via zoonotic transmission (de Lima Barros et al., 2011a,b; Bonifaz and Vazquez-Gonzalez, 2010; Lopes-Bezerra, 2018). The most common sites of infection are the skin and lymph nodes, and infection typically results in ulcers, nodules, and abscesses. Less frequently, the mucous membranes, bones, and joints may be involved and rarely, dissemination to the lungs, the central nervous system (CNS), and other organs may occur. Classically, sporotrichosis is known as “rose gardener’s disease” because it is typically spread by sapronotic transmission, the inoculation of tissue by contaminated plant materials. However, an emerging species of *Sporothrix*, *S. brasiliensis*, is transmitted to humans and animals by cats and is expanding through Brazil and into neighboring South American countries (Cordoba et al., 2018; Etchecopaz et al., 2019; García Duarte et al., 2017; Orofino-Costa et al., 2017; Rodrigues et al., 2020).

A brief history of sporotrichosis

The first confirmed report of human sporotrichosis is attributed to Benjamin R. Schenck, in 1898, when he was a medical student at Johns Hopkins University in Baltimore, USA (Schenck, 1898). Previously, in 1809 and in 1889, Link and Lutz reported probable cases of the disease but did not provide microbiologic evidence (Link, 1809; Rippon, 1988). Hektoens and Perkins used the name *Sporothrix schenckii* for the first time when they reported the second case, also in the United States, in 1900 (Hektoen and Perkins, 1900). In 1903, Beurmann and Ramond reported the same disease in France and the organism was named *Sporotrichum beurmanni*, by Matruchot and Ramond (De Beurmann and Ramond, 1903; Matruchot, 1910). Over time, hundreds of cases were described in France and the resulting literature serves as the classic characterization of sporotrichosis (de Beurmann and Gougerot, 1912). The first zoonotic cases of sporotrichosis were described in Brazil in 1907 following rat bites, and in 1909, zoonotic cases caused by horses were documented in Madagascar, caused by the equine isolate *S. equi* (Carougeau, 1909; Lutz and Splendore, 1907). Zoonotic cases of sporotrichosis were infrequently reported throughout the 20th century, until the emergence of cat-transmitted sporotrichosis caused by *S. brasiliensis* in the 1990s (Marques et al., 1993; Schubach et al., 2001).

The pathogenic species of the genus sporothrix

Taxonomic studies

Sporothrix is not considered a complex of cryptic fungal species, but rather a single genus with genetic, ecological, and biological diversity (Lopes-Bezerra et al., 2018). The fungi that cause sporotrichosis are currently classified in the Kingdom Fungi, Subkingdom Dikarya, Phylum Ascomycota, Class Euascomycetes, Order Ophiostomatales, Family Ophiostomataceae, Genus *Sporothrix*, and includes around 53 species (de Meyer et al., 2008; Rodrigues et al., 2020). This fungus is widely distributed in nature, including in soil, water, and decomposing organic material such as sphagnum moss, thorns, wood, and dry leaves (de Lima Barros et al., 2011a, b; Chakrabarti et al., 2015a). Human and animal sporotrichosis is caused by *S. schenckii*, *S. globosa*, *S. brasiliensis* and *S. luriei*. These form the “pathogenic or clinical clade” of medical and veterinary importance, while several non-pathogenic species are grouped in an “environmental clade” (Lopes-Bezerra et al., 2018; Rodrigues et al., 2020). Notably, sapronotic species from diverse environmental clades, such as *S. mexicana*, *S. pallida*, *S. humicola* and *S. chilensis*, may infect mammals, but these infections are uncommon and have little epidemiological relevance for this disease (Table 1).

Table 1 The clinical and environmental clades of *Sporothrix* species.

Clinical clade		Environmental clade	
Clade I	<i>S. brasiliensis</i>	Clade V	<i>S. pallida</i>
Clade II	<i>S. schenckii</i>	Clade IV	<i>S. mexicana</i>
Clade III	<i>S. globosa</i>		
Clade VI	<i>S. luriei</i>		

S. schenckii is the most extensively distributed of the species. It has been found in North, Central, and South America, Southern Africa, Australia, and Europe. *S. brasiliensis* is confined to Brazil and Argentina but has the potential to spread to other South American countries (Chakrabarti et al., 2015a; Cordoba et al., 2018; Etchecopaz et al., 2019; Gremião et al., 2017). This fungal species is unique among those that cause endemic mycoses because it has the biological capacity for transmission while in the yeast phase. Unlike other *Sporothrix* spp., *S. brasiliensis* does not undergo a dimorphic transformation phase during mammal infections (Gremião et al., 2017; Queiroz-Telles et al., 2017). *S. globosa* has a more limited geographic distribution, with cases occurring predominantly in Asia, particularly in China and Japan. The least common etiology of sporotrichosis among the “pathogenic clade” is *S. luriei*. Isolated cases of *S. luriei* have occurred in South Africa, India, Italy, and Brazil (Ajello and Kaplan, 1969; Alberici et al., 1989; Oliveira et al., 2011; Padhye et al., 1992).

Molecular phylogeny

Several publications have reported the relationship between *Sporothrix* genotypes and their geographical distribution. *Sporothrix globosa* from Brazil, China, Japan, Spain, and the United Kingdom are closely genetically related, suggesting that they have a common ancestor (Rodrigues et al., 2013b; Zhang et al., 2015). Plant debris is hypothesized to be a major source of the pathogen, and sporotrichosis has been called “reed toxin” in regions with extensive sapronotic transmission (Yu et al., 2013). *Sporothrix* cannot be classified to the species or clade level using only macroscopic and microscopic characteristics. Distinguishing these species by phenotypic similarities has led to misidentification of *Sporothrix* species in the past. However, the development of novel molecular techniques has led to advances in fungal epidemiological studies. These novel approaches led to the discovery that *S. schenckii* was actually composed of several distinct species with a common ancestor (Rangel-Gamboa et al., 2016; Rodrigues et al., 2013b).

Over decades, two common techniques have been used for phylogenetic study: amplified fragment length polymorphisms (AFLP) and restriction fragment length polymorphisms (RFLP) (Ishizaki et al., 2009; Neyra et al., 2005). Internal transcribed spacers (ITS), chitin synthase, β -tubulin, and calmodulin genes are the loci most commonly used in these studies. Based on the sequence of calmodulin (a highly conserved protein, important as an enzymatic cofactor in fungal calcium-calcineurin signaling pathways), *S. schenckii* is considered a complex of phylogenetically related, cryptic species (Marimon et al., 2006, 2007). Two groups of *S. schenckii*, *sensu lato* (*s. l.*) and *sensu stricto* (*s. str.*), were differentiated, with *S. schenckii sensu lato* (*s. l.*) signifying the species complex, while *sensu stricto* (*s. str.*) specifies the exact species (Rangel-Gamboa et al., 2016).

It is noteworthy that phylogenetic analysis is accompanied by different conidia morphology, biochemical characteristics, and ecological behaviors. *S. schenckii* and *S. globosa* have been isolated from humans, various animals, and soil (Marimon et al., 2006, 2007), whereas *S. brasiliensis* has been isolated primarily from humans, cats, and dogs (Rodrigues et al., 2013b).

Epidemiology

Geographical distribution, incidence and prevalence

Sporotrichosis is the most widespread implantation mycosis in the world. It has been reported on all continents, but the principal endemic areas for this disease are Latin America, India, South Africa, Japan, China, and Australia. The incidence and prevalence of this condition are difficult to determine because it is not mandatory to report. However, the prevalence has been estimated to range from 0.1 to 0.5% (Bongomin et al., 2017; Chakrabarti et al., 2015a; Queiroz-Telles et al., 2017). Sporotrichosis is hyperendemic in some geographic regions, like Albacay, Peru, with an incidence rate ranging from 48 to 98 cases/100,000 (Lyon et al., 2003; Pappas et al., 2000; Ramirez-Soto et al., 2012), and in Jalisco and Puebla, Mexico with a prevalence of 25 cases/100,000 (Bonifaz et al., 2007; Estrada-Castañón et al., 2018; García Vargas et al., 2008). Other hyperendemic areas can be found in Colombia, Venezuela, Brazil, China, and Japan (Bustamante and Campos, 2001). There are few reports of sporotrichosis from Europe, and most are from people who traveled or immigrated to endemic areas. The European countries with most reported cases are France, Italy, and Spain (Alberici et al., 1989; Criseo et al., 2008; Magand et al., 2009; Ojeda et al., 2011; de Oliveira et al., 2014). Other scattered case reports have been published from Asia and the Pacific Islands, including Thailand (Kwangsukstith et al., 1990; Tovikkai et al., 2020), Indonesia (Campbell, 1965), Korea (Kim et al., 2019), Laos (Newton et al., 2005), and New Zealand (Black et al., 1968) (Fig. 1).

Clusters and outbreaks

Although most of the *Sporothrix* infections are isolated and scattered around the globe, several clustered cases and outbreaks have been reported in diverse regions over time (Hay and Morris-Jones, 2008). The largest ever recorded sapronotic sporotrichosis outbreak occurred in the gold mine of Witwatersrand, in South Africa, when approximately 3300 miners were infected via fungus-infested wood timbers between 1938 and 1947 (Brown et al., 1947). Interestingly, a more recent investigation in 2011 found 81 new cases in another South African gold mine (Govender et al., 2015).

Currently, the largest and longest zoonotic sporotrichosis outbreak is related to transmission from cats in several Brazilian geographic regions, and it has recently expanded into neighboring countries in South America (de Lima Barros et al., 2004; Cordoba et al., 2018; Etchecopaz et al., 2019; Gremião et al., 2017; Rodrigues et al., 2020).

This outbreak involves cat-to-human transmission (zoonotic transmission) and animal transmission, mainly cat-to-cat and cat-to-dog. The zoonotic and epizootic transmission of *S. brasiliensis* started at the end of the 1990s in the state of Rio de Janeiro, Brazil

Fig. 1 Global distribution of sapronotic and zoonotic sporotrichosis. Proven zoonotic infections caused by *S. brasiliensis* and *S. schenckii* were defined as clinical isolates obtained from human and/or feline patients identified to species by molecular methods. Probable *S. brasiliensis* infections were based on clinical and epidemiological evidence, including feline microbiologic identification, but lacking species identification by molecular methods.

and is estimated to involve about 5000 humans, 8000 cats, and nearly 300 dogs (Gremião et al., 2020). This data is certainly underestimated because reporting sporotrichosis cases is not compulsory in Brazil.

Interestingly, small outbreaks and isolated cases of cat-transmitted sporotrichosis have been reported from several other countries since 1952. Unlike the outbreak in Brazil, zoonotic transmission was associated with *S. schenckii* in these other countries, including the United States, Mexico, Argentina, Spain, Germany, India, Australia, Japan and Malaysia (Gremião et al., 2017) (Fig. 1)

Source of infection and routes of transmission

The natural habitat of *Sporothrix* species appears to be soil and plant material, as cellulose, vegetable detritus, wood, and leaves can serve as an important nutritional substrate for fungal growth (Bongomin, 2018; de Lima Barros et al., 2011a,b). Occasionally, environmental strains have been isolated from pastures and other environmental sources as well (McGuinness et al., 2016).

Many isolates have been reported in the United States from sphagnum moss, which is used in gardening, particularly with bonsai trees and pine crops. Most of the environmental and clinical isolates have been identified in temperate and humid climates, with an average temperature of 20–25°C and relative humidity above 90% (Dixon et al., 1991; Hajjeh et al., 1997). *Sporothrix* spp. are often thermotolerant, with some species being found in temperatures from 2°C to 6°C (Jilin, China), while others have been adapting to warmer climates, such as in western Mexico and parts of southern Brazil (Almeida-Paes et al., 2009; Moussa et al., 2017). *Sporothrix* can grow in a pH range of 3.5–9.6. Sporotrichosis occurs at all times of the year, but in the northern hemisphere cases are seen more often in late autumn and early winter. This is thought to be due to the timing of the rainy season and harvest for certain crops, particularly corn. *Sporothrix* spp. have been isolated from the roots and stems of corn crops in China (Song et al., 2013).

Sporotrichosis can also be acquired from animals that act as indirect or passive vectors, the most common source being the domestic cat (*Felis catus*). There are several reports of sporotrichosis associated with injuries caused by other animals, such as rodents (rats, mice, gophers and squirrels), horses, mules, donkeys, cattle, camels, chimpanzees, boars, dogs, foxes, dolphins, fishes, parrots, other birds, and the nine-banded armadillo (Alves et al., 2010; Kwon-Chung and Bennett, 1992; Rodrigues et al., 2016b; Saravanakumar et al., 1996; Seyedmousavi et al., 2018).

However, there are also recorded cases attributed to insect bites, animal scratches, and the bites of reptiles, spiders, and bats (Rodrigues et al., 2016b; Zhang et al., 2015). *S. brasiliensis* is the only species in the *Sporothrix* genus that is saprozoönotic—existing in environmental reservoirs while easily infecting a mammalian host. *S. brasiliensis* is the only dimorphic fungus with the biological capacity for transmission directly from the yeast phase, and the high fungal load of yeasts harbored in lesions of infected cats facilitates transmission (Gremião et al., 2017; Macedo-Sales et al., 2018; Queiroz-Telles et al., 2017). Human infection may occur after traumatic, transcutaneous inoculation caused by feline scratches and bites, but also via non-traumatic routes, such as direct contact between the mucocutaneous secretions of sick animals and a host's mucous membranes or damaged skin (Gremião et al., 2017; de Miranda et al., 2018).

Most cases of sporotrichosis are the result of cutaneous inoculation, through trauma with contaminated material. It has also been proven that in individuals living in highly endemic areas, the fungus can enter the airways via inhalation, leading to pulmonary manifestations and many asymptomatic infections, or even penetrate through the various mucous membranes, including through the tarsal conjunctiva. It is also important to note that the zoonotic transmission of *S. brasiliensis* may result

from direct fungal contact with the host's integumental barriers, even without evidence of trauma (Almeida-Paes et al., 2014; Schubach et al., 2005a; Yamagata et al., 2017).

Occupation

Sporotrichosis is considered an occupational disease, with most cases seen among agricultural workers, horticulturists, gardeners, forestry workers, carpenters, hunters, miners, and fishermen (Chakrabarti et al., 2015b). However, cases have also been seen among housewives and school-age children (Lyon et al., 2003; Pappas et al., 2000). For cat-transmitted sporotrichosis, veterinarians, veterinary technicians, and cat owners (especially those who own many cats) are at increased risk of *S. brasiliensis* infection (Brandolt et al., 2018; de Carvalho Aguinaga et al., 2014; Gremião et al., 2017).

Sex and age

The distribution by sex may vary by geographic region. Most authors give a sex ratio of 1:1. However, during the Brazilian zoonotic epidemic, a few reports noted a marked predominance of sporotrichosis among women, while in another series, more cases were seen among men (de Lima Barros et al., 2011a,b). The age distribution is broad, but two incidence peaks are frequently reported: in school-age children (5–15 years, 30% of cases) and young adults (16–35 years, 50% of cases). In the hyperendemic area of Peru, 50% of cases occur in children under 15 years old. However, the disease can be seen at all ages, from newborns to the elderly (de Lima Barros et al., 2008; de Lima Barros et al., 2011a,b).

Incubation period

The length of the incubation time is multifactorial. The inoculum dose, isolate's virulence, and the integrity and capability of the host's defenses all contribute to the incubation period. For cutaneous and lymphocutaneous forms of sporotrichosis, the time from inoculation to clinical manifestation may vary from 1 to 4 weeks. For the extracutaneous clinical forms, the incubation period is uncertain (Bonifaz and Tirado-Sanchez, 2017; Tirado-Sánchez and Bonifaz, 2018).

Risk factors

For sapronotic sporotrichosis, the risk factors for acquiring this disease are related to occupation, and in the case of zoonotic infections, risk factors relate to contact with feral and domestic cats. However, the more severe and disseminated clinical forms of sporotrichosis are also associated with malnutrition, chronic alcoholism, agricultural pesticide exposure, uncontrolled diabetes, TNF- α blockers, steroid therapy, hematologic malignancies, solid organ transplant, and HIV-AIDS (Gewehr et al., 2013; Moreira et al., 2015; Queiroz-Telles et al., 2019).

Pathogenesis and host defenses

Virulence factors

To survive in the hostile environment of a host organism, microbes developed structures and factors to evade the host's defense mechanisms. Most of the virulence-related factors observed in sporotrichotic infections are similar to those studied for other pathogenic fungi.

Thermotolerance

The cutaneous and systemic infectivity of yeast forms of *S. schenckii* were characterized in 5–10-week-old male BALB/c mice by inoculation via their hind footpads and intraperitoneal routes. The study showed strong infectivity in the subcutaneous layer but not via hematological routes. The inoculation of mice with lung isolates via the intraperitoneal route was found to result in death within 117 days. The less virulent isolate demonstrated slow growth of *S. schenckii* at 37°C. Regarding thermotolerance, this study also agreed with the previous evidence that infection with isolates grown at 37°C could cause multiple lesions on internal organs. However, it is still uncertain if heat susceptibility is a virulence factor. Later, the thermotolerant mutant of the lung isolate demonstrated a slow growth rate of ≥ 4 days at 37°C, compared with the parent strain lung isolate, by repeat plating to verify the virulence factor. These mutant isolates were capable of infecting the skin but did not lead to disseminated infections in mice (Tachibana et al., 2001). There was additional evidence to show that the growth of *S. schenckii* was inhibited at $\geq 37^\circ\text{C}$ and halted at $\geq 39^\circ\text{C}$ in vitro during susceptibility testing (Castro et al., 2013).

Cell wall

The cell wall is a pathogen's first line of defense, but the cell wall can also trigger the innate immune system. Novel cell wall structures from two common pathogenic *Sporothrix* spp., *S. schenckii* and *S. brasiliensis*, were analyzed using high-pressure freezing

transmission electron microscopy (HPF-TEM). In a murine model, *S. brasiliensis* showed more virulence than *S. schenckii* (Castro et al., 2013; Lopes-Bezerra, 2018). Glycoconjugates, β -1-3 and β -1-6 glucans, and chitin are presented and functioned as pathogen-associated molecular patterns (PAMPs) and triggered secretion of specific cytokines. The α -glucan polymer, which blocks β -glucans from dectin-1 recognition in other dimorphic fungi, is absent in *Sporothrix* spp. Both *S. schenckii* and *S. brasiliensis* have a bilayered cell wall. However, the cell wall of *S. brasiliensis* has 30% more chitin and 100% more rhamnose and rhamnomannan than *S. schenckii*, making the outermost fibrillar layer in *S. brasiliensis* significantly thicker than that of *S. schenckii*. The fibrillar layer can adhere to other yeast cells to build cellular network, whereas the fibrillar layer of *S. schenckii* detaches from the cell wall as it ages. After these isolates were assessed for their interaction with human macrophages, greater phagocytic activity was shown for *S. brasiliensis* than *S. schenckii*, and both species demonstrated a significantly greater uptake of 4-day-old cells over 10-day-old cells (Lopes-Bezerra, 2018). The lipid component of the *Sporothrix* cell wall is also reported to inhibit phagocytosis, as well as limit the stimulation of NO and TNF- α release (Lima et al., 2001).

Adhesins

The ability of the fungal cell to adhere to endothelial and epithelial cells is crucial to the invasion of host tissues. Adhesins support the binding of yeast cells to the dermal matrix, especially fibronectin. Moreover, adhesin has also been reported to have a major role in host immuno-modulation, which is explained in the immune response section (Castro et al., 2013). In *Sporothrix*, both the conidia and yeast forms are able to recognize three major glycoproteins in extracellular matrix: fibronectin, laminin, and collagen type II (Lima et al., 1999, 2001). Glycoprotein of 70 kDa (Gp70) is the main adhesin detected in all mice with sporotrichosis (Ruiz-Baca et al., 2009). By Western blot analysis, Gp70 was recognized together with the positive bands of fibronectin in the range of 37–92 kDa. This finding was confirmed by the co-localization of fibronectin and Gp70 on the yeast cell surface (Castro et al., 2013). There is some evidence that the fungus also has integrins or adhesin molecules with lectin-like domains that recognize human fibronectin at several points on the molecule (Lima et al., 2004). Expression of these molecules in *S. schenckii* is likely related to their virulence, because a higher level of expression was observed in the infective mycelial phase than in the parasitic yeast form. These adhesins can allow fungi to attach to human endothelial cells causing infection without tissue injury in vitro. Moreover, fungi are able to cross the intercellular space, resulting in bloodstream infections and hematogenous dissemination (Figueiredo et al., 2004).

Melanin

This pigment is broadly found in nature and is a common virulence factor in many pathogenic fungi, including *Sporothrix*. The major melanin, DHN-melanin in hyphae, can be synthesized without precursors, whereas eumelanin in hyphae and pheomelanin synthesis require precursors, such as 3,4-dihydroxy-L-phenylalanine (L-DOPA) or L-tyrosine (Jacobson, 2000; Langfelder et al., 2003; Nosanchuk and Casadevall, 2003). The role of melanins on minimum inhibitory concentration (MIC) of antifungal agents (terbinafine, itraconazole, ketoconazole, and amphotericin B) in type strains and clinical isolates of *S. brasiliensis* and *S. schenckii* was evaluated using the precursors 3,4-dihydroxy-L-phenylalanine (L-DOPA) and L-tyrosine, and the three melanin inhibitors—tricyclazole, glyphosate, and sulcotrione, according to CLSI protocol M38-A2. A twofold decreasing MIC for ketoconazole was found in each strain of *S. brasiliensis* and *S. schenckii* in the presence of L-tyrosine. A twofold decreasing MIC for terbinafine in the presence of tricyclazole was found in *S. brasiliensis* and type strains of *S. schenckii*. Regarding the Minimum Fungicidal Concentration (MFC), twofold decreasing MIC for amphotericin B in the presence of all inhibitors was observed in *S. brasiliensis* but not in *S. schenckii* or for other antifungal agents. These results indicated that melanin is protective for *S. brasiliensis* and *S. schenckii*. However, more studies should investigate these interactions in other *Sporothrix* species (Almeida-Paes et al., 2009; Madrid et al., 2010; Romero-Martinez et al., 2000).

Ergosterol

This crystalline steroid alcohol is a major compound in fungal cell membranes (Schroeder, 1984). The putative product of the H₂O₂-dependent enzymatic oxidation of ergosterol, known as ergosterol peroxide, can be found in *S. schenckii* (Sgarbi et al., 1997). This compound can be converted to ergosterol when in contact with an enzyme extract from the fungus. This molecule is able to inactivate or scavenge toxic oxygen products found in phagocytic cells (Basaga, 1990; Sgarbi et al., 1997). This finding indicates that ergosterol peroxide in *S. schenckii* plays a role as a protective mechanism to evade reactive oxygen species (ROS) during phagocytosis (Carnero et al., 2018). However, the ergosterol peroxide activity of *S. schenckii* after phagocytosis also relies on other detoxification strategies (Carlos et al., 2009).

Proteins

Several types of proteins are involved in fungal virulence. In *Sporothrix*, extracellular cell wall glucanase, a vesicle-associated protein, promotes fungal virulence by inducing the lysis of macrophages and other host cells (Tamez-Castrellón et al., 2020). Superoxide dismutase (SOD), a cell wall protein, promotes the growth and survival of pathogens under oxidative stress conditions, such as those inside macrophages and other cells (Rossato et al., 2018; Téllez et al., 2014). Certain proteinases, such as Proteinase I, are

associated with the ability of *Sporothrix* to invade the dermis by damaging skin (Rossato et al., 2018). Differences in protein expression are the primary factors contributing to the differing virulence among *Sporothrix* species. A study of 60 proteins found that higher levels of 9 specific proteins were associated with evasion of the host immune system in *S. brasiliensis* and *S. schenckii* when compared to *S. globosa*: aminopeptidase I, extracellular cell wall glucanase, Mn-superoxide dismutase, glyceraldehyde-3-phosphate dehydrogenase (GAPDH), heat shock 70-kDa protein 1/8, hydroxymethyl-glutaryl-coenzyme A (HMG-CoA) lyase, acetyl-CoA hydrolase, progesterone binding protein, and rhamnolipid biosynthesis 3-oxoacyl-(acyl-carrier-protein) reductase (Rossato et al., 2018). In contrast, non-virulence exoantigens such as secreted proteins of 46, 60, 90, and 110 kDa are commonly secreted at similar levels by *S. schenckii*, *S. brasiliensis*, and *S. globosa* (Fernandes et al., 2013).

Biofilms

Similar to other pathogenic fungi, *Sporothrix* is able to form biofilms in vitro and in vivo, overwhelming the host's defenses and decreasing the effectiveness of antifungal therapy (Mitchell et al., 2016; Tournu and Van Dijck, 2012). In general, fungal biofilms may promote adhesion on biotic or abiotic surfaces, helping the community of fungal cells to survive in hostile environments. Regarding the immune response, biofilms assist cells in resisting neutrophil attacks and avoiding ROS triggering (Hernandez-Chavez et al., 2017).

In a study involving *S. schenckii*, *S. brasiliensis*, *S. globosa* and *S. mexicana*, Brillhante et al demonstrated that all species are able to form well-structured biofilms in vitro in the mycelial phase (Brilhante et al., 2018). The formation of biofilm-like structures is believed to occur in the yeast-like form as well. Human and feline patients with severe and disseminated clinical forms of this disease may have a slow response to therapy or develop refractory disease due to *Sporothrix* biofilm formation (Brilhante et al., 2018; Mialski et al., 2018).

Innate host defense

To infect the host, fungi need to break down the host's first line of defense, such as skin or mucous membrane. The innate host defense provides the rapid recognition of a broad spectrum of pathogens through pattern recognition receptors (PRRs) and PAMPs (Janeway, 2002). The innate immune response plays a key role in the response to fungi, including *Sporothrix* (Carlos et al., 2009). So far, little is known about the PAMPs of *Sporothrix*.

Phagocytosis by macrophages and neutrophils, together with the production of ROS, are the major innate host defenses in response to *Sporothrix* spp. (Martinez-Alvarez et al., 2014; Mora-Montes et al., 2015). It is of note that each form of *S. schenckii* and *S. brasiliensis* (conidia, germings, and yeasts) are recognized by different receptors on the surface of host immune cells. The complement system is another immune defense triggered by *S. schenckii*. The alternative complement pathway is the most effective pathway for activating fungal phagocytic activity, via C3b component deposition on the fungal cell wall. Membrane attack complex (MAC) also plays a role in fungal cell lysis (Scott et al., 1986; Torinuki and Tagami, 1985).

To date, several publications emphasized the significance of toll-like receptors, especially TLR-2 and TLR-4, in sporotrichosis. In mice models in vivo, the absence of TLR-2 enhanced the dissemination of both *S. schenckii* and *S. brasiliensis* after 14 and 28 days of infection and stimulated the Th-17 response to control the infection (Rossato et al., 2019b). The in vitro results matched observations in vivo and supports the hypothesis that the impairment of TLR-2 after *Sporothrix* infection leads to insufficient macrophage activation. This also decreases nitric oxide synthesis, which is an essential micro-biocide molecule in the fungicidal activity of macrophages (Godaly et al., 2001). Similar to TLR-2, a deficiency of TLR-4 leads to a weakened immune response to both *S. schenckii* and *S. brasiliensis* infections. Moreover, the oxidative burst in response to *Sporothrix* spp. is not activated without TLR-4, further inhibiting the host immune response (Rossato et al., 2019a).

Cellular response

The components of a pathogen's cell wall play a major role in immune activation. In *Sporothrix* spp. infections, T-helper 1 and T-helper 17 responses are triggered by the secretion of certain cytokines, including IFN- γ , TNF- α , and IL-17A. These cytokines can stimulate both the innate and adaptive immune systems. IFN- β is considered the most important cytokine in the Th1 response against sporotrichosis because it is responsible for macrophage activation. In the Th17 response, IL-17A is the major cytokine secreted, as it activates macrophages and helps maintain epithelial barriers. The Th17 response is also essential for recruiting natural killer (NK) cells and mounting antifungal defenses (Bozza et al., 2002; Kajiwaru et al., 2004; Uenotsuchi et al., 2006).

To date, several antigenic peptides have been reported as immunodominant molecules in *Sporothrix* infections. Of the antigenic peptides, ZR3, ZR4, and ZR8 are all able to induce cellular proliferation, whereas only ZR3 and ZR8 have the capacity to induce IL-17A and IFN- γ . ZR8 can also induce the secretion of IFN- β , and IL-1 β , neutrophil proliferation in the lesion, and increased CD4⁺ T cells in the lymph nodes (with increased levels of IFN- β) and spleen (de Almeida et al., 2018). At this stage, Fc gamma receptor (Fc γ R) pathogen opsonization by antibodies also mediates macrophage functions to stimulate cytokine secretion and respiratory burst activation (Franco Dde et al., 2012). In the presence of antibodies against Gp70 glycoprotein, the fungicidal ability of macrophages is increased, and there are increased levels of TNF- α , IL-1 β , IL-6, and the anti-inflammatory cytokine IL-10 (Franco Dde et al., 2012). This leads to improved phagocytosis of the *Sporothrix* cells.

Dectin-1 is a receptor involved in cytokine production in sporotrichosis. This receptor must be triggered by 1,3- β -glucans, which are present on the fungal cell wall. Even though all morphological forms of *Sporothrix* can induce cytokine production, the strongest cytokine response is demonstrated in response to conidia, rather than yeasts or germlings (Guzman-Beltran et al., 2012; Martinez-Alvarez et al., 2017).

Humoral response

In the past, the cell-mediated immune response (CMI) was believed to be the major mechanism for fungal infection control, whereas humoral immunity (HMI) was not thought to play a role in combatting pathogenic fungi. However, HMI is now understood to play a critical role. The involvement of antibodies in a host's defense against fungal infection has been reported, although several factors affect its efficiency, such as antibody concentration and isotype (Almeida-Paes et al., 2007; Portuondo et al., 2016). Several mechanisms of HMI have been described: agglutination of fungal cells, opsonization and enhancement of phagocytosis, inhibition of fungal cell attachment, complement activation and mediated lysis, neutralization of immunoregulatory molecules, Fc-mediated cytokine release, and antibody-dependent cellular cytotoxicity (ADCC) (Portuondo et al., 2016). In sporotrichosis, little is currently known about the importance of HMI (Almeida-Paes et al., 2007; Rodrigues et al., 2015). However, an antibody-mediated response may provide some measure of protective immunity, based on murine models (Almeida, 2012; Almeida-Paes et al., 2007; Rodrigues et al., 2015).

Both CMI and HMI play an important role in protecting the host. In short, cytokines IL-4 and IL-13 induce T-cell differentiation from Th0 to Th2, and they decrease the Th1 response at 5–6 weeks after infection (Maia et al., 2006). In parallel, antibody production is triggered (Alba-Fierro et al., 2016; de Lima Barros et al., 2011a,b). This finding indicates that HMI plays a role in the advanced stages of sporotrichosis (Carlos et al., 2009). Based on an in vitro study, antibodies were also shown to have an effect on *S. schenckii* growth and differentiation (Toledo et al., 2010). These results were also found in vivo; a monoclonal antibody against 70 kDa adhesin induced an immune response against *Sporothrix* in mice (Nascimento et al., 2008). Moreover, it has been reported that murine models of *S. schenckii* infection can produce specific IgG1 and IgG3 antibodies against 70 kDa protein. This finding could explain the role of the antigen neutralization mechanism, because IgG1 and IgG3 are involved in opsonization and neutralization of *Sporothrix* spp. by enhancing macrophage efficiency. The administration of monoclonal antibodies also led to a significant decrease in colony forming units (CFUs) in mouse organs (Nascimento and Almeida, 2005). The same finding was demonstrated in T-cell deficient mice (nude mice). This confirmed that antibodies are able to control an infection in the absence of a T-cell response. The antibodies seem to function through two mechanisms: (1) increasing the CMI and IFN- γ production and (2) inhibition of yeast adhesion to host tissues and extracellular matrix (Alba-Fierro et al., 2016; Nascimento et al., 2008; Toledo et al., 2010).

In humans, IgG, IgM, and IgA antibodies have been demonstrated in patients with sporotrichosis. The antibody levels were reported to decrease during the treatment process, and differences between antibody level and clinical manifestations have been described. Lower optical density (OD) values for IgM and IgA were detected between cutaneous and extracutaneous forms of sporotrichosis, whereas no significant difference was present between disseminated cutaneous and extracutaneous forms. The presence of these antibodies affects the process of pathogen elimination. While IgM can activate complement by the classical pathway, IgA can prevent mucosal infections (Almeida-Paes et al., 2007).

Clinical aspects

The clinical presentations of sporotrichosis may be divided into two main categories: cutaneous and extracutaneous. However, in patients with zoonotic sporotrichosis, a wider and more diverse spectrum of clinical manifestations can be found.

Cutaneous sporotrichosis

Lymphocutaneous

Lymphocutaneous infections are the most common form of sporotrichosis, observed in 50%–70% of cases. The most common sites of infection are the upper and lower limbs and face, and lesions typically appear within days to weeks of infection. Initially, a papular skin lesion develops at the site of inoculation, which can evolve into a nodule or ulcer, known as the “sporotrichosis chancre.” This is characterized by swelling, erythema, and nodular lesions with erythematous halos, accompanied by itching. Subsequently, the lesions spread in a linear and staggered fashion along the regional lymph vessels towards the lymph nodes, which is described as “sporotrichoid spreading”. Nodular or fluctuant lesions tend to ulcerate. In chronic cases, it is observed that some lesions can self-involute. Occasionally and through multiple inoculations, it can form a mycetoma-like lesion, characterized by increased volume due to lymph stasis. Among children, this form is more commonly located on the face (up to 40% of cases). It may occur unilaterally or bilaterally, depending on the inoculation zone (Bonifaz and Tirado-Sanchez, 2017; Bonifaz and Vazquez-Gonzalez, 2010) (Fig. 2).

Fig. 2 Fixed cutaneous (A and B) and lymphocutaneous with ascending lymphangitis (C and D) clinical forms

Fixed cutaneous

The fixed cutaneous form is a chronic manifestation which occurs in 20%–40% of cases. It may be a single lesion or multiple lesions, depending on the number of implanted sites. It begins similarly to the lymphocutaneous form: with a single vegetative or warty lesion with defined edges and an erythematous-violet halo, and it is usually covered with flakes and meliceric scabs. Other than these isolated lesions, this form is often considered asymptomatic, and there is no lymphatic spread of the fungus (de Lima Barros et al., 2011a,b; Bonifaz and Vazquez-Gonzalez, 2010) (Fig. 2).

Disseminated cutaneous

The disseminated cutaneous manifestation (also known as cutaneous-hematogenous sporotrichosis) is rare (1%–5%). It is generally considered a unique entity and is associated with host risk factors and several types of immunosuppression, including HIV. The morphology is similar to the previously described forms, with a predominance of nodular, suppurative lesions, ulcers, and warty plaques located anywhere on the skin and mucous membranes of the nose, mouth, pharynx, and glans. Disseminated forms tend to spread to the bones and joints (monoarthritic), as well as to other organs, and may include fungemia and CNS involvement. Patients co-infected by HIV are more likely to develop disseminated forms of sporotrichosis (Bonifaz et al., 2018a; Bonifaz and Tirado-Sanchez, 2017) (Fig. 3).

Extracutaneous sporotrichosis

Ocular involvement

Although manifestations involving the eye and adnexa are rarely reported, the number of cases with ocular involvement has increased in Brazil since the start of the zoonotic outbreak of *S. brasiliensis*. It typically arises from fungal implantation in external ocular adnexa, like the conjunctive, cornea, and palpebra, rather than endogenous dissemination. Infection may occur after bites or scratches, or even after contact with mucocutaneous secretions from cats infected with *S. brasiliensis* yeast-like cells (de Lima Barros et al., 2004). The most commonly reported clinical manifestations are granulomatous conjunctivitis, but a wide spectrum of ophthalmologic manifestations have been reported. They include dacryocystitis, keratitis, granulomatous uveitis and retinitis, choroiditis, scleritis, necrotizing retinochoroiditis endophthalmitis and Parinaud's oculoglandular syndrome (Biancardi et al., 2017; Freitas et al., 2014; Kashima et al., 2010). Less frequently, blindness and eye enucleation are sequelae to choroiditis and endophthalmitis, respectively (Cartwright et al., 1993; Ramirez-Soto et al., 2018). Ocular involvement is also frequently reported in HIV patients with associated sporotrichosis (Moreira et al., 2015; Silva-Vergara et al., 2012) (Fig. 4).

Osteoarticular involvement

Manifestations of this disease in the bones and joints may follow systemic dissemination or direct implantation of the fungus. This may result in isolated osteomyelitis, with or without arthritis. Bone involvement has been observed in the knee, hands, and feet, as

Fig. 3 Cutaneous disseminated sporotrichosis in immunocompromised hosts. Multiple erythematous, papular and ulcerative necrotic lesions in an uncontrolled diabetic patient (A). Erythematous plaques and verrucous lesions in both thighs of a patient with alcohol use disorder (B). Ulcerative necrotic lesion in the face of a patient with medullar aplasia due to organophosphate pesticide exposure (C). Disseminated cutaneous ulcerated lesions (D and E) and noduloulcerative skin lesions in patients with HIV (F).

Fig. 4 Eye involvement related to *Sporothrix brasiliensis* infections in Brazilian patients. Granulomatous tarsal conjunctivitis in the left eye (A and B) and granulomatous conjunctivitis with preauricular adenopathy (C and D), also known as Parinaud oculoglandular syndrome.

well as isolated to the tibia, radius, and ulna. Lesions are painful with localized erythema and swelling. Radiologic images may present findings similar to bacterial osteomyelitis, with lytic lesions, bone erosion, osteopenia, and periosteal reaction (de Lima Barros et al., 2011a,b; McLawhorn et al., 2019; Orofino-Costa et al., 2010; Saeed et al., 2019).

Pulmonary involvement

This is a rare, although possibly underdiagnosed, clinical manifestation. Most pulmonary cases are primary infections, and all have been reported among people living in highly endemic areas (Pluss and Opal, 1986; Tiwari and Malani, 2012). There are two forms of pulmonary involvement: chronic and acute. The most common form is chronic, which is typically observed in patients with obstructive pulmonary disease or chronic alcoholism. This form manifests similarly to tuberculosis, with persistent productive cough, fever, night sweats, chills, and weight loss. Oligosymptomatic patients present with a self-limited disease including pulmonary cavitory lesions very similar to tuberculosis, while symptomatic patients present with a pneumonia-like illness with discrete coughing and little expectoration. Radiologic findings include areas of condensation or miliary opacities (Comstock and Wolson, 1975). The second form of pulmonary involvement is acute and progressive (associated with immunosuppression), presenting with a ring-like lymph node (tracheobronchial disease), and large adenopathies that cause bronchial obstruction. This form may be accompanied by general malaise, weight loss, a cough with abundant expectoration, hemoptysis, dyspnea, and fatigue. Radiologic findings may include adenopathy and mediastinal widening (Aung et al., 2013; Comstock and Wolson, 1975).

Neurological involvement

The CNS may be primarily or secondarily affected from systemic dissemination. Primary CNS involvement is more likely to occur in immunocompetent hosts, while hematogenous dissemination is associated with immunosuppression, as with HIV co-infection (Freitas et al., 2015; Galhardo et al., 2010). Neurologic involvement in sporotrichosis is rare, but the number of cases has increased since the zoonotic outbreak of *S. brasiliensis* in Brazil (Almeida-Paes et al., 2014). Chronic meningitis is the most common clinical manifestation and is easily confused with tuberculosis, which can lead to delayed diagnosis and treatment for many patients. The patients may complain of long duration of symptoms, insidious and refractory headaches, seizures, neurologic focal signs, ataxia, and mental confusion. Late diagnosis can result in the development of intracranial hypertension and hydrocephalus (Kauffman, 2019; Mialski et al., 2018).

Immunoreactive clinical forms

Some patients with cutaneous sporotrichosis may present clinical dermatologic and/or rheumatologic immunoallergic manifestations, resulting from a hypersensitivity reaction to circulating antigens. Up to 30% of the patients with zoonotic *S. brasiliensis* infections may present immunoreactive forms of sporotrichosis, including cutaneous rash, papular eruptions, erythema nodosum, erythema multiforme, reactive arthritis, and other dermatologic presentations (de Lima Barros et al., 2011a,b; Papaioordanou et al., 2015; Queiroz-Telles et al., 2017) (Fig. 5).

Opportunistic disease

The clinical manifestations of endemic mycoses in immunocompromised hosts can be quite remarkable. The weakened inflammatory and immune responses of immunosuppressed patients typically result in high fungal burdens, greater frequency of disseminated and severe clinical manifestations, and higher mortality rates. Endemic fungi in immunocompromised hosts often show false negative results by serology and typically require prolonged periods of antifungal therapy (Carvalho et al., 2002; Queiroz-Telles et al., 2019). Patients with several risk factors or underlying conditions are likely to present with more severe clinical forms of sporotrichosis with different varying degrees of severity. Over 100 sporotrichosis cases associated with AIDS have been reported, and most of them have been caused by *S. brasiliensis* in Brazil (Freitas et al., 2012; Mialski et al., 2018). Patients with low CD4+ levels and high viral loads may present cutaneous disseminated disease, fungemia, meningitis, pneumonia, or

Fig. 5 Immunoreactive clinical forms. Erythematous confluent papular lesions causing Sweet's syndrome (A) and reactive arthritis (B), in patients with *Sporothrix brasiliensis* infections.

endophthalmitis, with mortality rates of up to 30% (Moreira et al., 2015). Like some other fungal infections, refractory sporotrichosis may be associated with CARD9 deficiency (Bao et al., 2019) (Fig. 3).

Feline sporotrichosis

While sporotrichosis has been reported in a variety of animal species, the most significant and frequent animal infections occur in cats (Pereira et al., 2014). The epidemiology of feline sporotrichosis differs by the infecting *Sporothrix* spp. Feline infections caused by *S. schenckii* have occurred on five continents, and cases are typically isolated or limited to small outbreaks (Gremião et al., 2017; Hirano et al., 2006; Mackay et al., 1986; Pereira et al., 2014; Scheufen et al., 2015; Singer and Muncie, 1952). However, the emergence of *S. brasiliensis* has led to long-lasting epizootics of feline sporotrichosis through the South and Southeast regions of Brazil, as well as smaller outbreaks in other regions of Brazil and Argentina (Etchecopaz et al., 2019; Gremião et al., 2017; Schubach et al., 2005b). There has also been a documented case of travel-associated feline sporotrichosis in Paraguay (García Duarte et al., 2017). The ongoing outbreak of feline sporotrichosis in Brazil presents a serious threat for zoonotic transmission; accurate and rapid identification of feline cases is necessary to limit human exposures.

Feline sporotrichosis occurs most often among unneutered, male cats (Pereira et al., 2014), and infection typically occurs following traumatic inoculation via the scratch or bite of an infected cat (Rodrigues et al., 2016b). The clinical manifestations of feline sporotrichosis can range from subclinical to fatal disseminated infection (Schubach et al., 2004). Cutaneous manifestations are most commonly seen with multiple distinct nodular or ulcerated lesions occurring across the body. The most common sites of infection include the head and limbs, with frequent involvement of the nasal mucosa (Pereira et al., 2010; Schubach et al., 2004). In addition to cutaneous involvement, respiratory signs such as coughing and sneezing are frequently reported, and the presence of respiratory signs or nasal mucosal lesions are associated with treatment failure (Boechat et al., 2018; Pereira et al., 2010) (Fig. 6).

The most commonly used treatment for sporotrichosis in cats is itraconazole at 50–100 mg/cat/day (de Souza et al., 2018). In cases of therapeutic failure or recrudescence, the addition of potassium iodide at 2.5–20 mg/kg/day as a combination therapy can be effective (Gremião et al., 2015; Reis et al., 2016; da Rocha et al., 2018). To prevent cases of feline sporotrichosis among domestic pets, cat owners should prevent their cats from interacting with feral cats by keeping them indoors.

Differential diagnosis

Sporotrichosis must be differentiated from several infectious and non-infectious conditions. Patients presenting with cutaneous and extracutaneous clinical disease, as described above, should be carefully interviewed about previous injury from or contact with

Fig. 6 Clinical and microscopic characteristics of *Sporothrix brasiliensis* in cats. (A) Cutaneous ulcerated lesion in a cat paw. (B) Granulomatous palpebral conjunctivitis in the right eye. (C) Disseminated cutaneous ulcers and mucosal lesions with nasal involvement ("Clown-nose" lesion) causing open-mouthed breathing. (D) Several yeast cells in a skin biopsy. plants and animals. In endemic areas where *S. brasiliensis* infections are prevalent, a detailed history about cat contact should be collected. According to the clinical form or organ involvement, sporotrichosis must be differentiated from the following conditions:

Lymphocutaneous sporotrichosis

Cutaneous lymphatic leishmaniasis (Pian-bois), phaeohyphomycosis, ganglionic tuberculosis, syphilis, pyogenic infections, tuberculoid leprosy, and non-tuberculous mycobacterial infections (*M. marinum*), cat-scratch disease, filariasis, and others (Tirado-Sánchez and Bonifaz, 2018).

Fixed cutaneous sporotrichosis

Warty tuberculosis, chromoblastomycosis, eumycetoma and actinomycetoma, granulomatous dermatophytosis and candidiasis, cutaneous leishmaniasis, papilloma and verrucae, orf, yaws, botryomycosis, impetigo, infections by mycobacteriosis (*M. fortuitum* and *M. marinum*), sarcoidosis, psoriasis, systemic lupus erythematosus, mossy foot, squamous cell carcinoma, Bowen's disease, mycosis fungoides and others (de Lima Barros et al., 2011a,b; Bonifaz et al., 2007).

Disseminated cutaneous sporotrichosis

Cutaneous spreading of systemic mycoses (paracoccidioidomycosis, coccidioidomycosis, histoplasmosis, cryptococcosis, talaromycosis, and emergomycosis), tuberculosis and non-tuberculous mycobacteria, syphilitic gums, and others (Bonifaz et al., 2018a; Bonifaz and Tirado-Sanchez, 2017).

Pulmonary involvement

Endemic pulmonary mycosis, chronic aspergillosis tuberculosis and other mycobacteriosis, bacterial and viral pneumonia (Aung et al., 2013).

Ocular involvement

There are several bacterial, viral and fungal infections that may mimic ocular and eye adnexa sporotrichosis, including *Fusarium* and *Aspergillus* keratitis, hordeolum, chalazion, and others.

Neurologic involvement

All causes of chronic meningitis, including CNS tuberculosis and CNS mycosis (Kauffman, 2019).

Laboratory diagnosis

Direct examination and stains

Direct observation and conventional stains are of little use, because yeasts are not typically observed in lymphatic and cutaneous fixed sporotrichosis. With immunofluorescence techniques, fungi can be better identified. In general, mycological structures are noted in 5%–10% of cases. The yeasts appear as round to oval “cigar” or “boat-like” shapes. They are almost always isolated, so it is difficult to find them. However, in disseminated disease, immunosuppressed patients, and sick cats, multiple clusters of yeast are often seen (Orofino-Costa et al., 2017; Rudramurthy and Chakrabarti, 2017) (Fig. 6).

Culture

Fungal culture is the gold standard for diagnosis. Cultures can be made with samples from the exudate of lesions, abscess aspirates, scales, tissue fragments, synovial fluid, and sputum. The samples can be plated on Sabouraud dextrose agar with antibiotics and incubated at 28°C. Colonies appear in an average time of 5–8 days. All species of *Sporothrix* are dimorphic fungi, so yeast colonies can be obtained in rich culture media (blood agar, BHI agar, etc.) and incubated at 37°C. Colonies of the various species of *Sporothrix* develop rapidly (3–5 days), and they are membranous, radiated, and whitish or beige. The colonies later produce air mycelium-type coremium, maintain a mucoid appearance on the periphery, and turn dark brown in color due to melanization. The species *S. pallida* and *S. chilensis* are unique in that they do not generate melanic pigment (Cruz Choappa et al., 2014; Rodrigues et al., 2013a, 2016a) (Fig. 7).

Fig. 7 Mycological diagnosis. Macroscopic characteristics of *Sporothrix* spp. cultures in the mycelial phase (A and B). Some isolates may be melanized with time and become brown to black pigmented like the two rightmost tubes in (A) and the plaque colony in (D). The micromorphology shows thin hyaline septate hyphae with sympodial conidiophores (bouquet shape) forming right angles with the mycelium. Erytosin stain X 200 (C). In some isolates, conidia may become brownish due to melanization. Cotton blue X 400 (E).

Histopathology

Similar to direct mycologic exam, the histopathologic findings are not pathognomonic. The tissue response is non-specific and usually depicts a granulomatous, suppurative, and pyogenic reaction, consisting of micro-abscesses of polymorphonuclear cells and sometimes tuberculoid granulomas with enbibed histiocytes, lymphocytes, and Langhans giant multinucleated cells. In a study of 119 sporotrichosis cases, 84% had suppurative granulomas, while the rest were tuberculoid, foreign body-type, caseous, and fibrinoid granulomas. Yeasts and asteroid bodies were observed in 35% of cases (Quintella et al., 2011; Zhang et al., 2011). With unique stains of PAS and Gomori-Grocott, a few scattered growing yeasts can be observed. Rarely, typical “asteroid bodies” can be observed. This eosinophilic “spike like” structure results from the “Splendore-Hoeppli” immune-reaction, consisting of antigen-antibody immuno-complexes and cellular debris deposits surrounding the yeast cell wall (Daniel Da Rosa et al., 2008; Rodríguez and Sarmiento, 1998) (Fig. 8).

Immune tests

Serological screening has been improved to detect *Sporothrix*-specific IgG. Detection of circulating antibody is useful to differentiate sporotrichosis from other similar cutaneous diseases and to monitor the success of treatment. The most sensitive tests are the immunoenzymatics (ELISA) and Western blot methods, but neither are commercialized (Bernardes-Engemann et al., 2015; Orofino-Costa et al., 2017). Due to the common antigenic properties of *S. schenckii*, *S. brasiliensis*, and *S. globosa*, cross reactivity is seen when performing these tests (Rodrigues et al., 2020). A latex agglutination test to diagnose sporotrichosis meningitis has been developed and evaluated. The sensitivity and specificity of the test is high, but the availability of the test is still limited (Blumer et al., 1973).

An intradermal reaction test with sporotrichin was employed in the past to evaluate the endemicity of sporotrichosis (Bonifaz et al., 2018b). The test uses a polysaccharide metabolic fraction (peptide-rhamnomannan) of *S. schenckii* and is cross reactive with *S. brasiliensis* and *S. globosa*. Although it is highly specific (94.5%), it is neither standardized nor commercially available (Bonifaz and Vazquez-Gonzalez, 2013). It should be emphasized that this method is not authorized in some European countries or the United States.

Molecular diagnosis

This rapid DNA detection provides high sensitivity (83%–92%) and specificity (95%). Molecular diagnostics overcome the limitations of direct and histopathological exams, and they can facilitate surveillance efforts in outbreak scenarios. Different PCR

tests have been developed for major targets such as the ITS region, calmodulin, β -tubulin, and EF-1 α (Rodrigues et al., 2020). No commercial kit is currently available. This molecular diagnosis approach can be applied in the samples collected from any lesion, such as skin scrapings, tissue biopsies, pus, lymph node aspirates, conjunctival swabs, bronchoalveolar lavages, central nervous fluid, blood, etc. In addition, molecular methods based on the calmodulin gene sequencing are fundamental for the species identification (Rodrigues et al., 2014).

With the advent of matrix-assisted laser desorption time of flight mass spectrometry (MALDI-TOF MS), rapid user-friendly tests have been developed to aid in the identification of fungi to the genus and species level. However, more work is needed to build the database and improve identification of *Sporothrix* spp. (Oliveira et al., 2015).

Antifungal susceptibility tests

To date, standard guidelines for antifungal susceptibility testing of the genus *Sporothrix* have not been established. By the in vitro test based on the Clinical and Laboratory Standards Institute (CLSI) reference protocol (CLSI, 2008), terbinafine was claimed to be the most effective drug for both yeast and mold forms of *Sporothrix* spp., whereas voriconazole and fluconazole displayed very low activity (Alvarado-Ramírez and Torres-Rodríguez, 2007; Rodríguez-Tudela et al., 2008). The frequency of *S. brasiliensis* with high MICs of itraconazole and amphotericin B has been reported over the time (Alvarado-Ramírez and Torres-Rodríguez, 2007; de Lima Barros et al., 2011a,b). Similar to *S. schenckii*, the MICs of amphotericin B are varied when compared to *S. brasiliensis* isolates (Borba-Santos et al., 2015; Espinel-Ingroff et al., 2017). The breakpoints for *Sporothrix* have not yet been established. To set up the epidemiological cut-off value, meta-analysis of antifungal susceptibility profiles among the genus *Sporothrix* are required.

Treatment

Although molecular identification is crucial for accurate identification of the species causing sporotrichosis, it is not needed to initiate therapy. Despite recent data suggesting different in vitro susceptibility of *Sporothrix* spp. to antifungals and higher MICs for *S. brasiliensis*, these findings have not been confirmed in animal models or in human patients (Bonifaz and Vazquez-Gonzalez, 2013; Kauffman et al., 2007; de Lima Barros et al., 2011a,b; Queiroz-Telles et al., 2017).

Itraconazole is the treatment of choice for sporotrichosis, particularly in lymphocutaneous and fixed cutaneous clinical forms. The clinical response rate of patients treated with itraconazole ranges from 80% to 100% (de Lima Barros et al., 2011a,b). Although several regimens of oral itraconazole have been proposed, including 100 mg/day or intermittent administration (400 mg/day for 1 week and 3 week break) as pulse therapy, we recommend itraconazole for fixed cutaneous or lymphocutaneous forms at doses of 200 mg/day, continuously for an average time of 3–6 months or for 2–4 weeks after clinical resolution. For the disseminated cutaneous form, the itraconazole dose may be increased up to 400 mg/day in two doses. Children are treated with 6–10 mg/kg/day (Bonifaz et al., 2007).

The best alternative therapy to itraconazole is terbinafine. This allylamine derivative shows better *in vitro* activity against *Sporothrix* spp., but there is less literature on its efficacy when compared to itraconazole. Terbinafine therapy should be used at 500 mg twice daily. Children may receive 125–250 mg/day in two doses (Francesconi et al., 2009). Another therapeutic option is a saturated solution of potassium iodide (SSKI), which was the standard therapy for sporotrichosis in the past (Macedo et al., 2015). Despite its effectiveness, SSKI is less tolerated than itraconazole or terbinafine, and its main side effects include gastritis, rhinitis, bronchitis, hives, erythema, metallic taste, and swelling of the salivary glands (Kauffman et al., 2007). The dosage of SSKI in adults is 3–6 g/day, and for children it is 1–2 g/day. SSKI is administered at an initial dose of 5 drops, three times a day and is increased daily by 5 drops, up to a maximum dose of 30–40 drops. Due to the bitter taste, it can be given with milk or fruit juice. The duration of therapy in the most common cases of sporotrichosis (lymphatic and fixed) is three months on average. It is advisable to continue treatment for an additional one or two months to avoid relapse (Sterling and Heymann, 2000).

Fluconazole at the dose of 400–800 mg/day is also indicated, but only as a second line therapy or when itraconazole and terbinafine are not available (Kauffman et al., 1996). Posaconazole is effective for treating sporotrichosis, but it has only been used in a small number of cases (Fernandez-Silva et al., 2012). Voriconazole and isavuconazole have high MICs against *Sporothrix* spp., so these triazoles are not indicated for sporotrichosis (Thompson and Wiederhold, 2010).

Amphotericin B formulations can be used for disseminated and severe forms of sporotrichosis, such as neurologic, pulmonary, osteoarticular, and systemic infections. Unlike the triazoles, amphotericin B can be used in pregnant patients requiring systemic therapy. The deoxycholate form should be used at a dosage of 0.7–1 mg/kg/day and the lipid formulations at 3–5 mg/kg/day. Once the acute course is finished, itraconazole can be continued at a maintenance dose (Kauffman et al., 2007).

Some patients with mild forms of sporotrichosis, especially the fixed cutaneous form, can be treated with local heat or thermotherapy. This treatment is recommended for minor cases of sporotrichosis as concomitant therapy, especially in pregnant patients (Kauffman et al., 1996).

For patients with immunoreactive forms, nonsteroidal anti-inflammatory drugs (NSAIDs) can be added to antifungal therapy. If patients are unresponsive to therapy or have immune reconstitution inflammatory syndrome (IRIS), prednisone at 20 mg/day should be given for limited period of time (de Lima Barros et al., 2011a,b; Papaioordanou et al., 2015; Queiroz-Telles et al., 2017).

Prevention

Similar to other mycotic diseases, there is no vaccine for sporotrichosis. As with other implantation mycoses, the best way to prevent this disease is to use protective measures to avoid transcutaneous trauma, especially in endemic areas. The use of shoes, gloves, and clothes may diminish the risk for infection. In the case of cat-transmitted sporotrichosis, individuals should avoid contact with sick cats. The control of zoonotic sporotrichosis involves antifungal therapy for infected animals and people, and isolation or euthanasia of infected animals. Castration has been suggested to control the spread of this disease among cats in hyperendemic zones.

Regarding vaccine development in sporotrichosis, it has been proposed that after infection or active immunization with whole cell or cell wall of *Sporothrix* spp., a specific immune response can be developed (Portuondo et al., 2016). In mouse models, specific IgG1 and IgG2a antibodies against cell wall proteins of *Sporothrix* spp. were produced after inoculation with aluminum hydroxide-adsorbed *S. schenckii* cell wall protein. The IgG2 antibodies are involved in several immune mechanisms, including complement fixation and binding to Fcγ receptors to stimulate phagocytosis and ADCC in mice (Portuondo et al., 2016).

Introduction

Dermatophytes are specialized filamentous fungi that are able to degrade keratin. They are the cause of most fungal infections of the skin, hair and nails. Three ecological groups of dermatophytes are distinguished: (1) the anthropophilic species whose natural habitat is man; (2) zoophilic species whose natural habitat is an animal, and which are responsible for the most frequent zoonoses and (3) the geophilic species whose natural habitat is the soil (Weitzman and Summerbell, 1995). Dermatophytoses vary depending on the body site and the causative agent. The disease is often described with the word “tinea” followed by a term for the particular infected body site (Degreef, 2008). The anthropophilic species are generally not inflammatory and have a chronic character. On the contrary, zoophilic and geophilic species cause inflammatory fungal infections in humans (Fig. 1). Dermatophytosis is one of the most common zoonotic diseases. The main dermatophytes infecting humans are listed in Table 1 under anthropophilic, zoophilic and geophilic species.

The diagnosis of dermatophytosis cannot usually be made on the basis of clinical signs alone, but requires both direct microscopic examination of dermatological specimens and identification of the infectious species. Direct microscopic examination using fluorescence techniques is by far the most sensitive technique for detecting rare hyphae and spores in dermatological samples (Fig. 2) (Monod et al., 1989). However, non-dermatophyte fungi can be the infectious agent in onychomycosis (Monod et al., 2006; Verrier et al., 2012). A positive direct examination in a nail does not automatically signify that the fungus is a dermatophyte.

Early clinical description of dermatophytes to species identification by PCR

The first dermatophyte species were described solely by the clinical appearance of the lesions and microscopic observation of the fungal nature of the infection. Schoenlein (1839) first reported the mycological nature of a ringworm caused by a dermatophyte. The fungus was named *Achorion schoenleinii* 6 years later by Remak (1845) and *Trichophyton schoenleinii* by Langeron and Milochevitch in 1930. Three other species were described by Gruby between 1841 and 1844. (1) *Trichophyton mentagrophytes*, which has been briefly described under the name of “mentagre,” with a Greek and Latin etymology meaning “plant caught on the chin” (mentum: chin; αἴρω: to catch; φυτόν: plant) for a beard mycosis (Gruby, 1842). (2) *Microsporum audouinii* for which the name was given in reference to small spores located along the hair in beard and scalp ringworms (Gruby, 1843). (3) *Herpes tonsurans* for scalp mycosis causing tonsures (Gruby, 1844). This third species was named *Trichophyton tonsurans* by Malmsten in 1845 and 1848. It results that *M. audouinii* and *T. tonsurans* are the type species of the genus *Microsporum* and *Trichophyton*, respectively, in the current dermatophyte nomenclature (de Hoog et al., 2017).

The first systematic study of dermatophytes was “Les teignes” published by Sabouraud (1910). Based on the clinical aspects of the lesions, direct mycological microscopy and culture examinations, Sabouraud classified dermatophytes into four genera: *Achorion*, *Trichophyton*, *Microsporum* and *Epidermophyton*. Emmons (1934) modernized the taxonomy proposed by Sabouraud and other authors. He classified the dermatophytes in three genera (*Trichophyton*, *Microsporum*, and *Epidermophyton*) based on the morphology of spores produced by the fungi in cultures, and eliminated the *Achorion* genus.

Fig. 1 Human dermatophytoses. (A) *Tinea barbae* with *T. mentagrophytes*. (B) *Tinea capitis* (kerion) with *T. benhamiae*, (C) *Tinea manuum* with *T. erinacei*. (D) *Tinea unguium* with *T. rubrum*.

Table 1 Ecological classification of the main dermatophytes infecting humans into anthropophilic, zoophilic and geophilic species.

Anthropophilic	Zoophilic ^a	Geophilic
<i>Trichophyton rubrum</i>	<i>Trichophyton mentagrophytes</i> (Cats, dogs, rodents (rabbits, mice, chinchilla), horses)	
<i>T. interdigitale</i>	<i>T. benhamiae</i> (Guinea pigs, dogs)	
<i>T. violaceum</i>	<i>T. verrucosum</i> (mainly cattle, but occasionally horses, pigs)	
<i>T. soudanense</i>	<i>T. erinacei</i> (hedgehogs)	
<i>T. tonsurans</i>	<i>T. quinckeanum</i> (Mice (favus))	
<i>T. schoenleinii</i>	<i>T. equinum</i> (Horses)	
<i>T. concentricum</i>	<i>T. simii</i> (Monkeys, poultry)	
	<i>T. bulbosum</i> (Horses, donkeys)	
<i>Epidermophyton floccosum</i>		
<i>Microsporum audouinii</i>	<i>M. canis</i> (Cats and other felines, dogs)	
<i>M. ferrugineum</i>	<i>Nannizzia persicolor</i> (Voles, shrewmouse, dogs)	
		<i>N. gypsea</i>
		<i>N. fulva</i>
		<i>N. incurvata</i>

^aHost reservoirs are in brackets.

Fig. 2 Direct mycological examinations of clinical and animal samples. (A) Hyphae in tinea corporis (bar = 10 μ m). (B) *Tinea capitis*, infected hair (bar = 40 μ m). One portion of each sample was examined in a dissolving solution containing a fluorochrome that specifically binds to vegetal and fungal cell wall polysaccharides (Monod et al., 1989). The sample preparations were observed using a fluorescence microscope using excitation between 400 and 440 nm.

Until the 1990s, macroscopic and microscopic characters of the fungus in culture identified the different species of dermatophytes. However, their identification in culture often remained uncertain due to the variations of morphological features within species. In addition, isolates of different species may have the same morphology. There was also a profusion of species and varieties for which no reference material (culture or strain) was deposited in a collection, creating great confusion in the delimitation and nomenclature of species. As early as the 1990s, the synonymy and distinction of species was made by DNA sequences (Gräser et al., 1999a,b). The polymorphism of the internal transcribed spacer sequences of the ribosome-coding DNA (ITS1 and ITS2) was first used to differentiate the species.

Last review of dermatophyte species and their nomenclature in 2016

de Hoog et al. (2017) have revised the taxonomy of dermatophytes based on the analysis of DNA sequences. A phylogenetic tree has made possible to clearly define the genera to which anthropophilic, zoophilic and exclusively geophilic species belong. The species of dermatophytes have been defined based on DNA sequences, on phenotypic characters observed in culture, on interfertility between strains and on their anthropophilic, zoophilic or geophilic character. A species is either anthropophilic or zoophilic, but not both. Geophilic species include many species that are not pathogenic to humans. The nomenclature was revised according to the newly defined genus, and according to the rules of the new convention adopted for the nomenclature of the fungi, where it was decided that a species could have only one name (de Hoog et al., 2015). The genus *Trichophyton* has been reduced to about 15 species, which are anthropophilic or zoophilic pathogens. *Epidermophyton* contains a single anthropophilic species, *Epidermophyton floccosum*. The genus *Microsporum* now contains only three species: *Microsporum canis* (zoophilic), *M. audouinii* and *Microsporum ferrugineum* (anthropophilic). Pathogenic geophilic species are in other distinct genera (*Nannizzia* and *Arthroderma*).

Identification of species in the laboratory

Dermatophyte species are generally identified by observing under the microscope: (1) the growth rate of the fungus in culture; (2) the appearance and color of the mycelium (Fig. 3); (3) the pigmentation of the agar and (4) the presence of microspores, microscopic macrospores and chlamydospores (Fig. 4). Anamnesis (age, ethnicity, housing, travel, contact with people of other nationalities, contact with animals, occupation) and clinical aspect of the lesions are essential to guide or confirm species identification.

In cases of uncertainty, strain identification can be performed by PCR using universal (panfungal) primers targeting ribosomal DNA (Ninet et al., 2003; Gräser et al., 1999a,b; Symoens et al., 2011, 2013). The most commonly used DNA sequences are those of the ITS1 and ITS2. The DNA sequence coding for the large 28S subunit of the ribosomes is also often used, but is less discriminatory. Species identification by PCR can be problematic using the public database of the National Center for Biotechnology Information (NCBI) (<http://www.nlm.nih.gov/>), which has weaknesses including identical sequences under different names, and different sequences under the same name. Specialized database is available in Mycobank (<http://www.mycobank.org/>).

It is also possible to identify dermatophytes as well as yeasts and molds directly in situ in a dermatological sample by PCR (Verrier and Monod, 2017; Verrier et al., 2012). In situ PCR techniques are particularly useful when the diagnosis of a mycosis has been made by a positive direct mycological examination or when the fungus does not grow (35% of onychomycosis cases). It is important to identify molds responsible of nail infections. Indeed, *Fusarium*, *Acremonium*, *Scytalidium* or *Aspergillus* onychomycosis are naturally insensitive to terbinafine and/or azole standard treatments (Baudraz-Rosselet et al., 2010; Lurati et al., 2011).

Dermatophyte species in culture can also be identified by MALDI-TOF MS (matrix-assisted laser desorption ionization time-of-flight mass spectrometry) (Nenoff et al., 2013; De Respinis et al., 2013, 2014). This technique allows the distinction between closely related species such as *Nannizzia gypsea*, *Nannizzia fulva* and *Nannizzia incurvata*. Unfortunately, it is not possible to identify infectious agents in situ in a clinical lesion using MALDI-TOF MS.

Change in prevalence of dermatophytes

The prevalence of dermatophyte species in populations varies with geography and continuously evolved from the middle of the 19th century until nowadays (Seebacher et al., 2008; Zhan and Liu, 2017). The evolution of urban and rural populations, migration from different continents, changes in the human lifestyle with the increasing number of pets and the emphasis on healing dermatophytosis in different countries are factors that make the reported frequency of dermatophyte species varies in a given location.

Trichophyton rubrum, which was only described in 1910 (as *Epidermophyton rubrum*) is now the dominant species in the world. This dermatophyte developed during the second half of this century. *T. rubrum* has supplanted *M. audouinii*, *E. floccosum* and *T. schoenleinii*, which were the main dermatophytes in the 18th and early 20th centuries. The two former species are now uncommon. The frequency of *M. audouinii* and *E. floccosum* is now in the range of 1–2% in Western Europe (Seebacher et al., 2008; Zhan and Liu, 2017) while *T. schoenleinii* has almost completely disappeared. The prevalence of *T. tonsurans* varies greatly with geography. The species is widespread in America (33–45%) in the United States (Seebacher et al., 2008; Zhan and Liu, 2017),

Fig. 3 Most frequently isolated dermatophytes species. (A): *T. rubrum*, (B) *T. interdigitale*, (C) *T. tonsurans*, (D) *N. gypsea*, (E) *T. benhamiae* (yellow phenotype), (F) *T. benhamiae* (white phenotype), (G) *T. mentagrophytes*, (H) *M. canis*, (I) *T. verrucosum*, (J) *T. soudanense*, (K and L) *T. violaceum*.

Fig. 4 Microscopic characteristics of various dermatophytes. (A) *T. mentagrophytes* microspores. (B) *M. canis* spindle-shaped, thick-walled macroconidia (bar in A and B = 10 μ m).

whereas, for example, it is infrequent in Switzerland with an incidence of about 1%. *Trichophyton violaceum* and *Trichophyton soudanense* are now frequently isolated in Europe from tinea capitis in patients of African and Mediterranean origin.

M. canis, *T. mentagrophytes*, *Trichophyton benhamiae* and *Trichophyton verrucosum* are the major zoophilic species. *M. canis* is the main zoophilic species and causal agent of tinea capitis and tinea corporis in Southern Europe (Seebacher et al., 2008; del Boz et al., 2011; Tsoumani et al., 2011; Otašević et al., 2019) like in many countries where stray cats and dogs are numerous. *T. benhamiae* is an emerging species in Europe with the increasing number of Guinea pigs as pets. The incidence of *T. verrucosum* has decreased significantly in many countries as the rural population has declined.

Dermatophyte teleomorphs

Only dermatophytes anamorphs (asexual fructifications) are isolated from clinical samples of infected patients, animals or soil. However, like *Aspergillus* spp., dermatophytes produce teleomorphs (sexual fructification), which are cleistothecia with prototunicate asci (Weitzman and Summerbell, 1995) (Fig. 5). Cleistothecia can be obtained by inoculating two isolates of different mating type (designated as either “+” or “–”) at a short distance (3 cm) at the center of a Petri plate containing an agar medium poor in substrate, for instance Sabouraud’s medium 1/10 or MAT (for mating) agar (Takashio, 1972; Kröber et al., 2017). All dermatophyte pathogenic species are heterothallic meaning that conjugation for sexual reproduction is only possible through the interaction of individual isolates of different mating type.

A bias of one particular mating type was observed in anthropophilic species where sexual reproduction has not been observed, as well as in zoophilic species. All isolates of the anthropophilic species *T. rubrum*, *T. tonsurans* and *T. interdigitale* were found of the—mating type. The latter was determined by sexual stimulation and pseudocleistothecia formation using an *Arthroderma simii* (now *Trichophyton simii*) tester strain of the opposite mating type (Stockdale, 1981). In the zoophilic species *T. benhamiae*, both mating types were isolated within a group of strains with a particular white phenotype, but only one mating type (–) was detected in a second group of strains that were characteristic by a yellow phenotype (Symoens et al., 2013).

Mating experiments and observation of fertile cleistothecia was a particularly helpful tool to delineate species of the *M. gypseum* (now *Nannizzia gypsea*) and of the *T. mentagrophytes* species complexes (Stockdale, 1961, 1963; Ajello and Cheng 1967; Takashio 1973, Demange et al., 1992; Symoens et al., 2011; Symoens et al., 2013). In this way, *T. interdigitale*, which is anthropophilic and generally isolated from tinea pedis and tinea unguium, was distinguished from *T. mentagrophytes*, which is zoophilic. Fertile cleistothecia could never be obtained from confrontations between isolates of *T. interdigitale* and tester strains of *T. mentagrophytes* (Symoens et al., 2011).

Dermatophytes with a + mating type were found to contain an *Hmg* gene coding for the mating type protein Mat1-2, while dermatophytes with a—mating type were found to contain an alpha box gene coding for the mating type protein MAT1-1 (Symoens et al., 2011, 2013). However, in other ascomycetes, the + mating type and the – mating type design strains with an alpha box gene and an *Hmg* gene, respectively. Li et al. (2010) adopted this designation when these authors characterized and compared the Mat-1 and Mat-2 locus of five dermatophyte species. During sexual development, two transcription factors, SteA and StuA, also play important functions. *T. benhamiae* mutated in one of these regulators makes only pseudocleistothecia (non-fertile cleistothecia) in mating experiments (Kröber et al., 2017).

Characteristics of the dermatophyte genomes

Pathogenic dermatophytes are closely related and their genomes are highly collinear (Martinez et al., 2012). The sizes of the genomes are between 22 and 24 Mb, which is small in comparison to the size of the genomes of saprophytic fungi such as *Aspergilli* (from 28–38 Mb) and *Neurospora crassa* (41 Mb) (de Vries et al., 2017). The number of predicted protein-coding genes varies from 7980 in *T. benhamiae* to 8915 in *M. canis* (Burmester et al., 2011; Martinez et al., 2012). Several distinguishing features characterize the genomes of the dermatophytes:

1. The presence of large gene families encoding secreted endoproteases of the subtilisin, deuterolisin and fungalisin families. Enrichment of families of secreted protease attests for the ability to better adapt to different environmental conditions such infection (parasite phase of the fungus) and hard keratin degradation (saprophyte phase of the fungus).
2. The depletion of genes coding for enzymes involved in the metabolism of sugars and the degradation of plant cell walls. For instance, there are no genes encoding glycoside hydrolases and alpha amylases.
3. The enrichment of genes encoding proteins containing one or several LysM domains known to be specific for binding chitin and N-linked oligosaccharides in fungal glycoproteins and in human skin. Protein expansion with a LysM domain could be related to the ability of the fungus to escape the immune system during infection.
4. The conservation of the genes involved in mating and meiosis in all dermatophyte species, suggesting interfertility of strains in same species in the environment.

Proteolytic activity of dermatophytes as saprophyte fungi

Pathogenic species of dermatophytes evolved from soil saprophyte fungi able to efficiently degrade hard keratin in the environment into amino acids and short peptides in the process of recycling soil nitrogen (Fig. 6). Microorganisms via membrane transporters can assimilate these products of proteolysis, but not large peptides or full-length protein (Payne and Smith, 1994). At neutral or alkaline pH in a medium containing protein as the sole source of carbon and nitrogen, dermatophytes secrete two major subtilisins (Sub3 and Sub4) and two major fungalisins (Mep3 and Mep4), which are endopeptidases (Jousson et al., 2004a,b; Sriranganadane et al., 2011). In addition, dermatophytes secrete aminopeptidases, e.g., leucine aminopeptidases (Lap1 and Lap2) and dipeptidyl peptidases (DppIV and DppV). In a protein medium at acidic pH, dermatophytes secrete an aspartic protease of the pepsin family (Pep1) as an endoprotease, as well as tripeptidyl peptidases of the sedolisin family, prolyl peptidases and carboxypeptidases of the MEROPS S10 family, as exoproteases (Sriranganadane et al., 2011). Dermatophytes secreted proteases show activities similar to those of orthologues enzymes secreted by *Aspergillus fumigatus* (Monod et al., 2005). This suggests mechanisms of extracellular proteolysis at acidic and neutral pH by dermatophytes comparable to those known in *Aspergillus* species (Byun et al., 2001; Sriranganadane et al., 2010). Endoproteases produce large free-end peptides from keratin, on which exoproteases can act to produce oligopeptides and free amino acids.

Fungal secreted proteases are incapable of digest by themselves hard keratin structures such the stratum corneum of skin, hair and nails. Proteases operate only after the reduction of cystine disulfide bridges, which are responsible for the resistant nature of hard keratin (Kunert, 1992, 2000). During the degradation of keratin, dermatophytes and filamentous fungi secrete sulfite as a reducing agent using a sulfite efflux pump (Ssu1) (Léchenne et al., 2007). Sulfite is a product of the metabolism of cysteine. In the presence of sulfite, disulfide bonds of the keratin substrate are directly cleaved into cysteine and S-sulphocysteine (Kunert, 1972, 1976, 2000; Ruffin et al., 1976) and after sulfitolysis, reduced proteins become accessible to further digestion by various *endo*- and *exo*proteases secreted by the fungi. *T. benhamiae* mutants in *Ssu1* were defective for growth on hair and nails in vitro (Grumbt et al., 2013). The same was also observed for mutants in the gene *Cdo1* encoding the cytoplasmic cysteine dioxygenase, which is involved in the intracellular conversion of cysteine into sulfite. Therefore, sulfitolysis is mandatory for the digestion of hard compact keratin by dermatophytes.

Fig. 6 The different steps of keratin degradation by dermatophytes.

Potential virulence factors of dermatophytes as parasitic fungi

Secreted proteases

Unexpectedly, most of the proteases secreted in vitro during keratin digestion appeared to be not secreted in onychomycosis and infection of guinea-pigs (Staib et al., 2010; Tran et al., 2016; Méhul et al., 2016). Therefore, one cannot consider these proteases as virulence factors by which dermatophytes penetrate keratinized tissues. During infection, dermatophytes secrete proteases other than those secreted in vitro in a protein medium. Transcriptome analysis performed with RNA from guinea pigs infected by *T. benhamiae* and proteomic analyzes of proteins extracted from infected nail beds of patients with tinea unguium revealed that a particular subtilisin (Sub6) was the major protease secreted during infection (Staib et al. 2010; Tran et al., 2016; Méhul et al., 2016, 2019). Sub6 was found to be a marker of *Trichophyton* onychomycosis by proteomics and Western blot analysis of proteins in nail samples. It is important to note that Sub6 has never been detected among the proteases secreted by *T. rubrum* and *T. benhamiae* in vitro. Additional proteins secreted by *Trichophyton* during nail infection were the closely related Sub7 and the dipeptidyl peptidase DppV. Sub6 and DppV were the major Tri r 2 and Tri r 4 dermatophyte allergens, respectively, that had previously been identified in patients with asthma (Woodfolk, et al., 1998).

Potential non-protease secreted proteins as possible virulence factors

Transcriptomics revealed in vivo overexpression of genes encoding proteins with functions other than proteolysis. ARB_01183 encoding a presumed antigenic protein of the thaumatin domain was the most highly expressed secreted protein-encoding gene in vivo (Tran et al., 2016). Thaumatin-like proteins (TLPs) are present in many eukaryotes and have been studied in plants, where they are involved in defense against fungi (Palacín et al., 2012). The role of thaumatin during infection is not known.

Two 1,3-beta-glucanotransferases encoded by ARB_07487 and ARB_05770 were also found up regulated during infection. 1,3-beta-glucanotransferases play an important role in fungal cell wall morphology and pathogenicity (Tran et al., 2016). The deletion of the gene *Gel2* encoding a 1,3-beta-glucanotransferase in *Aspergillus fumigatus* leads to a change in cell wall composition and a reduction in virulence in a mouse model of invasive aspergillosis (Mouyna et al., 2005).

Like the gene encoding Sub6, the genes encoding thaumatin and 1,3-beta-glucanotransferases were found to be highly upregulated during infection but not under in vitro conditions (Tran et al., 2016). Dermatophyte infections after a saprophytic lifestyle is achieved through extensive reprogramming of the expression of the genes encoding secreted proteins.

Proteins harboring LysM domains

A LysM (for Lysin Motif) domain is a small globular domain of approximately 40–65 amino acids with a structure composed of a pair of antiparallel beta strands separated by a pair of short alpha helices ($\beta\alpha\alpha\beta$ secondary structure) (Bateman and Bycroft, 2000; Buist et al., 2008). The LysM domains are found in proteins of bacteriophages, bacteria and eukaryotes allowing binding to peptidoglycan, chitin and carbohydrate ligands. They were first discovered as tandem repeats in the lysozyme of *Bacillus* phage $\phi 29$ (Garvey et al., 1986) and subsequently found in the peptidoglycan hydrolase of *Streptococcus faecalis* (Béliveau et al., 1991).

Two *T. rubrum* proteins of with three LysM domains (TERG_05627 and TERG_01873, respectively) were characterized after overexpression of their encoding genes in *Neurospora crassa* and in *E. coli* (Kar et al., 2019). Both proteins through their LysM domains bind to chitin, to N-linked oligosaccharides on fungal glycoproteins and to N-linked oligosaccharides in human skin glycoproteins. Therefore, the LysM dermatophyte proteins could be important in virulence by masking cell wall components of the pathogen's (chitin and/or glucans) on the surface of hyphae like in plant pathogenic fungi (de Jonge and Thomma, 2009) and helping the fungus to escape the innate immune system (Martinez et al., 2012). By binding to human skin glycoproteins, the LysM proteins could also function as adhesion proteins.

The expansion of LysM binding domains is a trademark of the dermatophyte genomes (Martinez et al., 2012). The *T. rubrum* genome contains six proteins containing two or more LysM domains (Kar et al., 2019). A role for LysM proteins in pathogenicity has also been suggested because members of gene families are a priori considered to be virulence factors in pathogenic microorganisms. The emergence of multigenic families is most often due to processes of gene duplication allowing organisms to better adapt to different environmental conditions. However, the role of LysM proteins as virulence factors remains hypothetical, as none has yet been identified during infection.

Clinical manifestations distant from dermatophyte infections: Asthma and skin dermatophytides

Dermatophyte infections may provoke secondary immune reactions such as eczematous skin reactions (dermatophytids) and severe asthma. Common dermatophytids are dyshidrotic and vesicular eczemas on the hands (palms and/or fingers) associated with tinea pedis and/or tinea unguium in adults, most caused by *T. interdigitale*, rarely by *T. rubrum* (Veien et al., 1994). Eczema on the chest, trunk and back (elsewhere on the body) has also been reported concomitantly with tinea capitis and tinea corporis caused by zoophilic and anthropophilic dermatophytes (Gianni et al., 1996; Liu et al., 2011; Cheng et al., 2011). Four diagnostic criteria were retained to conclude to a dermatophytid reaction (i) there is a proven dermatophyte infection in a body site other than the locus of the eczematous skin reaction; (ii) the eczema appeared after the dermatophyte infection and the fungus is not present in the

site of the cutaneous eruption. From this site, culture assays remain sterile and direct mycological examination is negative; (iii) the dermatophytid symptoms only resolve after eradication of the primary focus of fungal infection; (iv) the patients are sensitized to dermatophyte antigens and show a positive skin test response to fungal extracts (termed “Trichophytin”). Individual antigens involved in dermatophytids have not been identified.

Patients with *Trichophyton* asthma are also sensitized to dermatophyte antigens (Ward et al., 1989) and asthma improved after specific antifungal treatment (Platts-Mills and Woodfolk, 2009). Woodfolk et al. (1998, 2000) discovered and characterized two main allergens, Tri r2 and Tri r4, inducing both either immediate (IH) and delayed type (DTH) hypersensitivity skin test reactions in patients. These antigens are two proteases secreted during infection (see above). Tri r2 and Tri r4 were later renamed Sub6 and DppV, respectively, in the protease nomenclature of *T. rubrum* (Jousson et al., 2004b; Monod et al., 2005; Sriranganadane et al., 2011).

Immunity

Dermatophytosis is frequent and usually limited to the keratinized tissues: skin stratum corneum, nails and hairs. Anti-dermatophytes immunity knowledge has gained insight thanks to recent in vivo data and knowledge of acquired or inherited immunodeficiency predisposing to invasive dermatophytosis.

By contrast with superficial dermatophytosis limited to stratum corneum some individuals develop invasive dermatophytosis where dermatophytes invade dermis. Patients prone to develop invasive dermatophytosis have acquired immunodeficiencies including oral corticosteroids for solid organ transplantation (SOT), other immunosuppressive therapies, HIV infection, atopy, diabetes mellitus, Cushing's disease, congenital adrenal hyperplasia, hematologic malignancy, autoimmune diseases, liver disease, or trauma such as shaving (Rouzaud et al., 2015, 2018). Other patients at risk of developing invasive dermatophytosis have primary immunodeficiencies, including CARD9 deficiencies. (Lanternier et al., 2013). Defective pathways in SOT patients and CARD9 pathway should have a key role in anti-dermatophyte immunity. CARD9 deficient patients with deep dermatophytosis were evidenced to have a reduced number of IL-17 producing T cells, a reduced pro inflammatory cytokine production by dendritic cells and neutrophils recruitment to the site of infection. It was also evidenced in a recent animal model that Th1 and Th17 response were complementary to control superficial dermatophytosis (Heinen et al., 2019).

A recent publication evidenced that patients with chronic superficial dermatophytosis had an elevated IgE level, elevated Th17 and Treg cells, increased IFN- γ and IL-10 levels by comparison with controls (Rai et al., 2020). It was also shown recently in skin biopsies of patients with superficial dermatophytosis that the number of Langerhans cells were significantly decreased in the epidermis (Reis et al., 2019). Therefore, both innate and adaptative immunity have a major role in dermatophytosis control with involvement of Langerhans cells, Th17 and Th1 immunity.

Antifungal drugs against dermatophytes and antifungal resistance

The antifungals most commonly used to treat dermatophytosis are terbinafine, azole compounds, such as itraconazole and fluconazole, and griseofulvin (Hay, 2018). Terbinafine and azole compounds target the biosynthetic pathway of ergosterol (Leyden, 1998). A lack of ergosterol results in an alteration of the structure of the plasma membrane and its function (Leyden 1998; Odds et al., 2003). Griseofulvin inhibits fungal mitosis by disrupting the mitotic spindle through interacting with polymerized microtubules (Gull and Trinci, 1973). Although potentially toxic, griseofulvin remains the treatment of choice in many cases of tinea capitis (Hay, 2017, 2018) insensitive to terbinafine and azole compounds.

Increased exposure to drugs favors the generation of resistant microbes, and following this trend, dermatophytes resistant to antifungal drugs have emerged in several countries. Osborne et al. (2005, 2006) reported the two first cases of terbinafine resistance in *T. rubrum*. Since 2017, several cases of terbinafine-resistant onychomycosis, tinea pedis and tinea corporis with either *T. rubrum* or *T. interdigitale* were reported in both Europe and Asia (Yamada et al., 2017; Saunte et al., 2019). Such resistance was associated with a non-synonymous point mutation in the squalene epoxidase (SQLE) gene of *T. rubrum* and *T. interdigitale* (L393, F397, F415 and H440), the first two being predominant.

The occurrence of terbinafine-resistant *T. rubrum* mainly from nails and tinea pedis was estimated around 1.0% in Switzerland (Yamada et al., 2017). This contrasts with the prevalence of *T. mentagrophytes* isolates with a particular genotype (*T. mentagrophytes* type VIII), which are responsible for an ongoing epidemic of tinea cruris and tinea corporis in India (Nenoff et al., 2019). Depending on the studies, the prevalence of terbinafine-resistant isolates was comprised between 30% and 70% (Rudramurthy et al., 2018; Singh et al., 2018; Ebert et al., 2020). Most resistant Indian strains of *T. mentagrophytes* revealed SQLE with a point mutation identical to one of the mutations previously recorded in *T. rubrum* at positions 393, 397, 415 and 440. The amino acid substitution F397L was highly prevalent, till 91% among resistant isolates (Ebert et al., 2020). Three new substitutions, S395P, Q408L and S443P, were also recorded in the SQLE of resistant *T. mentagrophytes* isolates (Ebert et al., 2020).

One case of *T. rubrum* with reduced susceptibility to azoles has been found caused by overexpression of two genes (*MDR2* and *MDR3*) encoding a multidrug transporter of the ABC family (Monod et al., 2019). Among 39 ATP-binding cassette (ABC) transporters and 170 major facilitator superfamily (MFS) transporters identified in silico within the *T. rubrum* genome, 4 ABC transporters (TruMDR1, TruMDR2, TruMDR3 and TruMDR5) and 2 MFS transporters (TruMFS1 and TruMFS2) were able to operate

as azole efflux pumps when their encoding genes were overexpressed in *Saccharomyces cerevisiae*. TruMDR3 and TruMFS1 were able to act as an efflux pump toward fluconazole, itraconazole, ketoconazole, miconazole and voriconazole. TruMFS1 was also able to transport cycloheximide suggesting that acts as a pleiotropic drug transporter with a broad substrate spectrum. In contrast, TruMDR1 and TruMFS2 were found specific for fluconazole and voriconazole, which have a similar molecular structure. While resistance to azoles remains exceptional in *T. rubrum*, so far, about 15% of *T. mentagrophytes* type VIII isolates were less sensitive to itraconazole and voriconazole (Ebert et al., 2020). To date, we have no data on the possible azole resistance mechanisms in these isolates. The emergence of *T. mentagrophytes* type VIII strains resistant to both terbinafine and azole antifungal compounds is of concern.

The acquired dermatophyte resistances are not anymore exceptional. However, the identification of the infectious agent remains important in cases of nail and hair infections for the prescription of appropriate treatment because of the possible intrinsic resistance of the fungal infectious agent. For instance, standard treatments with terbinafine and azoles are inefficient in cases of onychomycosis with a non-dermatophyte mold, in particular *Fusarium* spp., *Acremonium* spp. and *Aspergillus* spp. (Baudraz-Rosselet et al., 2010; Lurati et al., 2011). Regarding dermatophyte species, many cases of tinea capitis with *M. audouinii* and zoophilic species such as *M. canis*, *T. benhamiae* and *T. mentagrophytes* do not respond to terbinafine and azole treatments (Baudraz-Rosselet et al., 1996; Hay, 2017, 2018). In such cases, the use of griseofulvin is required.

Introduction

The term “anisakiasis” or “anisakiosis” refers to the accidental human infection with the anisakid nematodes belonging to the genus *Anisakis*. This genus, giving the root name to the family Anisakidae, includes the most distributed nematodes in Boreal, Austral and Tropical marine ecosystems, around the globe. They are parasites at their larval stages of several fish species worldwide, even of commercial importance. As a consequence, the zoonotic disease is acquired by humans upon the ingestion of raw, undercooked or lightly processed fishery products. In the same family, other nematodes are considered as zoonotic to humans, i.e., some species of the genera *Pseudoterranova* and *Contracaecum*; the latter regarding only those species maturing in pinniped hosts. In the case of human infection with “anisakid nematodes” the term “anisakidosis” should be instead used. Due to the high distribution of *Anisakis* spp. in the marine realm and the number of human cases so far described due to *Anisakis*, we will focus on the species so far included in the genus *Anisakis* and the zoonotic disease due to the species *A. simplex* (s.s.) and *A. pegreffii*, which are those, at the time of this chapter writing, recognized as responsible for the human disease.

Taxonomy, morphology, life cycle of *Anisakis* spp.

Life cycle

Anisakis species have complex and heteroxenous life cycle which, generally speaking, involves various marine organisms at different levels of the trophic web in the marine ecosystem (Fig. 1). The adults live in the gastric chamber of marine mammals, mainly cetaceans (definitive hosts). Fish and squids are intermediate or paratenic hosts, while planktonic or semi-planktonic crustaceans act as first intermediate hosts. Female worms release fertilized eggs which are passed in the stools of their definitive hosts into the sea and lead to free swimming unsheathed larvae in the marine environment (Fig. 2). It has been generally accepted that the larvae undergo one or two molts before being ingested by the first intermediate invertebrate host (mostly small crustaceans, krill). These intermediate hosts (i.e., *Euphausia similis*, *Euphausia pacifica*, *Thysanoessa raschii*, *Nyctiophanes couchii*) (Gregori et al., 2015) (Fig. 2) harboring the third stage larvae (L₃) are then predated by a wide variety of paratenic hosts, such as squids and fishes, where the L₃ stage does not molt. Indeed, most of *Anisakis* L₃ stages remain in the visceral cavity of the fish encapsulated outside the visceral organs, whereas in other cases, parasites can migrate to the musculature of the fish (Roepstorff et al., 1993; Karl and Levsen, 2011; Cipriani et al., 2016) (Fig. 1). To this step, the infected fish may be directly eaten by the definitive host when the L₃ stage molts to L₄ stage and then matures to the adult form of the parasite. Alternatively, the fish may be eaten by another fish: the larvae re-encapsulate in this new host. This phenomenon may occur several times, inducing a potential accumulation of *Anisakis* spp.

Fig. 1 General life-cycle of *Anisakis* spp.

Fig. 2 Developmental stages of *Anisakis*. (A) Eggs with a L₁ stage larva; (B) Emerging 2nd stage larva from the egg; (C) Newly hatched L₂ stage larva; (D–F) 3rd stage larvae in the celomic cavity of first intermediate hosts; (G–I) 3rd stage larvae coiled outside the fish organs and free in the visceral body cavity of the fish; (J) muscle sections of a fish under the UV-Press system allowing to detect *Anisakis* larvae as bright fluorescent spots; (K) adults of *Anisakis pegreffii* in the first gastric chamber of a striped dolphin, *Stenella coeruleoalba*. (A–F) From Gregori M, Roura A, Abollo E, Gonzalez AF and Pascual S (2015) *Anisakis simplex* complex (Nematoda: Anisakidae) in zooplankton communities from temperate NE Atlantic waters. *Journal of Natural History* 49: 755–773.

larvae, in predatory fish, along the trophic web (Zuo et al., 2016; Munster et al., 2015). Despite the general pathway of the life cycle speculated by the species of the genus *Anisakis* is that reported in Fig. 1, some differences in ecological aspects regarding both host preference and geographical distribution of the so far recognized species in the genus, do exist (detailed in Mattiucci et al., 2018).

Molecular systematics and current taxonomy of *Anisakis* spp.

Molecular/genetic methodologies have revolutionized the taxonomy of the species of the genus *Anisakis* during the last 20–30 years (Mattiucci and Nascetti, 2008). The molecular/genetic markers so far available in *Anisakis* parasites, and based on the existing

literature, have aimed to: (1) disentangling sibling (cryptic) species; (2) establishing phylogenetic relationships between related taxa; (3) providing an intraspecific population analysis; (4) estimating their genetic diversity; (5) providing suitable markers for species identification at any stage of their life cycle; (6) study hybridization and/or introgression phenomena between closely related species.

Among the nuclear gene loci, the multilocus allozymes analysis allowed the discovery of all the so far genetically characterized species of *Anisakis* (see next paragraph) (reviewed in Mattiucci and Nascetti, 2008; Mattiucci et al., 2018). Later on, the direct sequencing of the ITS region of the rDNA and the RFLPs of the same gene loci, allowed their recognition by PCR-DNA methodologies (D'Amelio et al., 2000). Further, the recognition of all the species of *Anisakis*, as based on nucleotide diagnostic positions, as well as their phylogenetic relationship was inferred from the direct sequencing of the mitochondrial gene locus mtDNA *cox2* (Valentini et al., 2006). In recent years, other nuclear loci have been used in the identification of the *A. simplex* (s.l.) species complex. They are: the sequence analysis of the EF1 α -1 nDNA (Mattiucci et al., 2016); the *nas10* nDNA and the development of ARMS-PCR based on the same gene locus (Palomba et al., 2020b), as well the development of DNA microsatellite markers (SSRs) (Mladineo et al., 2017; Mattiucci et al., 2019), permitting to find additional diagnostic markers between those *Anisakis* species (Mattiucci et al., 2019; Bello et al., 2021). Several among the developed SSR loci resulted to be sex-linked in the three species of the *A. simplex* (s.l.) complex (Mattiucci et al., 2019; Bello et al., 2021).

As based on genetic/molecular systematics approach, starting from the Davey (1971) revision of the species of *Anisakis*, according to which only three species were considered as valid taxa: i.e., *A. simplex*, *A. typica* and *A. physeteris*, to date nine nominal species and two undescribed taxa are recognized in the genus *Anisakis*.

Indeed, the existence of nine species as distinct phylogenetic units was also demonstrated by various phylogenetic analyses, as inferred from nuclear and mitochondrial genes (Valentini et al., 2006; Mattiucci and Nascetti, 2008; Cavallero et al., 2011; Mattiucci et al., 2014a). According to those analyses, four distinct major clades within the genus *Anisakis* clearly exist. The clade 1 includes the three sibling species of the *A. simplex* (s.l.) complex: *A. simplex* (s.s.), *A. pegreffii* and *A. berlandi* (Fig. 3). A second clade is that formed by *A. ziphidarum* and *A. nascetti*; the two species are sister taxa. The species *A. physeteris* and its related genotype *Anisakis* sp. 2 (Mattiucci et al., 2018; Aco Alburquerque et al., 2020), *A. brevispiculata*, and *A. paggiae* (Fig. 3) are forming a third highly supported clade (Mattiucci et al., 2014a,b, 2018; Murata et al., 2011). Finally, phylogenetic inference obtained from the combined nuclear and mitochondrial sequences identified *A. typica* and its related *Anisakis* sp. 1 (Mattiucci and Nascetti, 2008; Mattiucci et al., 2014a; Mattiucci et al., 2014b; Mattiucci et al., 2018) as a separate lineage with respect to the other species (Mattiucci et al., 2018). However, the precise positioning of the *A. typica* clade is not yet clearly resolved from a phylogenetic point of view. Finally, phylogenetic hypotheses attempted for the species of the genus *Anisakis* with respect to the phylogeny so far proposed for their definitive cetacean hosts, have shown that co-divergence and host-switching events could have accompanied the evolution of these group of anisakid nematodes (Mattiucci and Nascetti, 2008) (Fig. 2).

Geographical distribution and host specificity of *Anisakis* spp.

Anisakis simplex (s.s.). This parasite species occurs in subarctic, and temperate waters of the Northern hemisphere approximately from 35°N to the Arctic Seas (Fig. 4). It has been recorded in both the Western and Eastern Atlantic and Pacific Oceans. Actually, *A. simplex* (s.s.) is a parasite, at the adult stage, of dolphin species belonging to the family Delphinidae, Monodontidae, Phocoenidae and whales in Balenopteridae. It is a parasite at the third stage of more than 50 pelagic, benthopelagic and demersal teleost fish and squid species mainly belonging to the family Ommastrephidae (Mattiucci et al., 2018). Its southern limit of distribution in the North-Eastern Atlantic waters is the Spanish-Portuguese Atlantic coast. The species occurs at a rare prevalence of infection in some fish species from the Morocco-Mauritania Atlantic coast. The southern limit of *A. simplex* (s.s.) distribution in the Pacific Ocean would be the coast of Japan, while in the eastern part, along the North American coast (Mattiucci et al., 2018), up to California waters (Baldwin et al., 2011). The species has been identified, at the larval stage, in the Mediterranean Sea, from the Alboran Sea, which is a basin considered as part of the Atlantic oceanographic waters rather than the Mediterranean Sea (Tintore et al., 1988; Mattiucci et al., 2014a,b). Spot occurrence of *A. simplex* (s.s.) in the eastern part of the Mediterranean Sea has been also reported (Blazekovic et al., 2015; Mladineo et al., 2017) as likely related to the large migratory route of those intermediate and definitive host species.

Anisakis pegreffii Campana-Rouget and Biocca (1955). Previously indicated as *A. simplex* A (see: Nascetti et al., 1986), *A. pegreffii* is a parasite, at the adult stage, in the oceanic dolphins belonging to the families Delphinidae, porpoises in Phocoenidae and whales in Neobalenidae. While, at its third larval stage, it occurs in pelagic and benthopelagic fish species (Mattiucci et al., 2018; Cipriani et al., 2021). *A. pegreffii* is the dominant species of *Anisakis* in the Mediterranean Sea (reviewed in Mattiucci et al., 2018). In the Atlantic waters, the northerly limit of its geographical range is represented by the Iberian coast, from where the species has been frequently identified in sympatry with *A. simplex* (s.s.) in intermediate/paratenic and definitive hosts (reviewed in Mattiucci et al., 2018). *A. pegreffii* is also widespread in the Austral Region, between 30°S and 60°S where the species was identified, at both adult and larval stages (Mattiucci et al., 2018, 2019; Irigoitia et al., 2018, 2021) (Fig. 4).

Anisakis berlandi (see Mattiucci et al., 2014a) previously indicated as *A. simplex* C in Mattiucci et al. (1997) is a parasite with a geographical range including mainly the Austral Region: Chilean Pacific Ocean waters, the South Shetland Islands, New Zealand waters and the South African Atlantic coast (Mattiucci and Nascetti, 2008; Klimpel et al., 2010; Mattiucci et al., 2018). It is a parasite, at the adult stage, mainly in cetaceans species belonging to the families Delphinidae, while its L₃ stage infects fish species from Austral waters from off New Zealand (Mattiucci et al., 2014a, 2019; Bello et al., 2020), South African, Southern Shetland Islands

Fig. 3 Phylogenetic inference (BI) of the *Anisakis* spp. Definitive hosts (cetaceans)—parasite association is also shown at the nodes of major clades. Morphological diagnostic features among the genetically characterized species of *Anisakis*, mapped into the major clades of the phylogenetic tree are reported.

(Klimpel et al., 2010), and the Southern Chilean coasts (Fig. 4). A benthopelagic life cycle of these parasites has been supposed (Irigoitia et al., 2021).

Anisakis ziphidarum Paggi et al. (1998). It is a parasite species at the adult stage of the beaked whales *Mesoplodon layardii*, *M. mirus*, *M. densirostris* and *M. grayi* from the South Atlantic waters (off South Africa coast), from *M. europaeus* of Caribbean sea (Colon-Llavina et al., 2009; Cavallero et al., 2011), from *M. bowdoini* of New Zealand waters (Mattiucci et al., 2009), *Ziphius cavirostris* from the South Atlantic Ocean (off the South African coast), from Chilean waters, and occasionally reported in *Kogia sima* from Philippine waters (Quiazon et al., 2013). Its geographical range is mainly related to the distribution of those definitive hosts (Fig. 4). It is rarely occurring, at the larval stage, in fish species (Mattiucci and Nascetti, 2008; Di Azevedo et al., 2016; Quiazon et al., 2011; Mattiucci et al., 2018).

Anisakis nascettii Mattiucci et al. (2009). It is a parasite species of the beaked whales, sympatrically and syntopically occurring with *A. ziphidarum*. Its larval stages were found in the deep squid species *Moroteuthis ingens* (Mattiucci et al., 2009). This appears to support the hypothesis that this species, such as the sister taxa *A. ziphidarum*, involves mainly squids rather than fish, in the life-cycle.

Anisakis physeteris Baylis (1920). This parasite has been reported, at the adult stage, from the sperm whale, *Physeter macrocephalus* from the Mediterranean Sea (Mattiucci et al., 1986, 2001; Blazekevic et al., 2015), and the Caribbean Sea (Colon-Llavina et al.,

Fig. 4 World map showing the current range of distribution of *Anisakis* spp.

2009; Cavallero et al., 2011). The infection has been also recorded in the pygmy sperm whale, *Kogia* spp., from the Caribbean Sea, Gulf of Mexico (Cavallero et al., 2011) and in the Mediterranean Sea (Santoro et al., 2018). Its Type II larvae have been rarely occurring in pelagic and demersal fish species (Mattiucci et al., 2018); while squid species belonging to the family Histioteuthidae from deep waters of the Mediterranean Sea have been found infected by larvae of *A. physeteris* (Palomba et al., 2021).

Anisakis brevispiculata Dollfus (1966). The species, previously synonymized with *A. physeteris* by Davey (1971), was recognized as valid species by molecular systematics (Mattiucci et al., 2001). Its adult stage occurs in the pigmy sperm whale, *Kogia breviceps*; its L₃ stage Type III (sensu Shiraki, 1974) were identified in the stomach lumen of the swordfish *Xiphias gladius* (Mattiucci et al., 2011, 2014b), in the fish *Beryx splendens* from Japanese waters (Murata et al., 2011) in fish from Taiwan (Chen and Shih, 2015) and Japanese waters (Quiazon et al., 2011).

Anisakis paggiae Mattiucci et al. (2005). It is a parasite species of pygmy sperm whales, *Kogia* spp. often found in sympatry and syntopy with *A. brevispiculata*. Its Type IV larvae (sensu Shiraki, 1974) have been identified in fish from Atlantic waters (Fig. 4), i.e., *Merluccius merluccius* and *Xiphias gladius* (Mattiucci et al., 2014a,b). The finding of its Type IV larvae in deep-sea fish seems to support an oceanic deep-water life cycle for *A. paggiae* in the North-East Atlantic Ocean (Klimpel et al., 2011).

Anisakis typica Diesing (1860). This species has a geographical range extending from 35° to 40° N to 36° S in warmer temperate and tropical waters (Fig. 4). In these areas, it was found as an adult in oceanic dolphins (Mattiucci and Nascetti, 2008; Colon-Llavina et al., 2009; Íñiguez et al., 2009, 2010; Kleinertz et al., 2014) and as larva in several fish species. It was also found in fish captured along the North African coast of the Mediterranean Sea (Farjallah et al., 2008), in central Portuguese waters of the NE Atlantic Ocean (Marques et al., 2006; Hermida et al., 2012), from the Atlantic Ocean off Madeira (Mattiucci et al., 2002; Hermida et al., 2012), and Morocco-Mauritania Atlantic coast (Farjallah et al., 2008). The species is reported also from the Central Pacific Ocean (Kuhn et al., 2013; Palm and Bray, 2014), the Red Sea (Kleinertz et al., 2014) and the Persian Gulf (Shamsi et al., 2017), East China Sea and Taiwan Sea (Zhu et al., 2007; Kong et al., 2015; Umehara et al., 2010; Quiazon et al., 2011; Chou et al., 2011; Chen and Shih, 2015), Yellow Sea (Du et al., 2010), Indonesia (Palm et al., 2008; Anshary et al., 2014) and from Papua New Guinea (Koinari et al., 2013). It seems that this species mainly involves pelagic fish hosts in its life-cycle.

Anisakis sp. 1. A gene pool, provisionally indicated as *Anisakis* sp. 1, genetically closely related to *A. typica*, was genetically detected by both allozyme and mtDNA analysis, at the larval stage, as a parasite of the fish from off the Malaysian coast (Mattiucci and Nascetti, 2008; Mattiucci et al., 2018). Likely, the same taxon was found by Palm et al. (2008), Koinari et al. (2013), Anshary et al. (2014), Quiazon et al. (2020), from Indonesia, Papua New Guinea and Philippines waters, respectively. The formal description of this provisional taxon, as a possible sibling species of *A. typica* was based on both genetic and morphological features, has not yet been performed.

Anisakis sp. 2 (see Mattiucci et al., 2014b). It seems to represent a further taxon, genetically closely related to the species *A. physeteris*. Adult stages of this taxon have been so far found in *Physeter macrocephalus* and swordfish from central Atlantic waters (Mattiucci and Nascetti, 2008; Garcia et al., 2011), and from fish from Central Pacific waters (Aco Alburquerque et al., 2020). Further genetic/molecular analyses are needed to clarify the taxonomic status of this genotype.

Morphological features of *Anisakis* species

The existence of distinct clades in the phylogeny of the species of the genus *Anisakis* seems to be also supported by some differential morphological features detected in the species clustering in those clades (Fig. 3). Similar morphological characters at the adult stage are quite maintained by the *Anisakis* species included in the same Clade, such as in the ratio between spicules length, as well as spicule shape, ventriculus length (see Mattiucci et al., 2018) (Fig. 3). Indeed, the four major clusters defined by the phylogenetic analysis correspond and can be also morphologically characterized with distinctive morphological traits in adult worms (for details, Mattiucci et al., 2018).

As to the morphological traits of third stage larvae (L_3) of the genetically characterized species of *Anisakis*, four different morphotypes, i.e., Type I, Type II (Berland, 1961), Type III and Type IV (Shiraki, 1974), have been found; however molecular/genetic markers are necessary for their specific identification. The L_3 indicated as a Type I morphology (sensu Berland, 1961) are shared by species of three species of the *A. simplex* (s.l.) complex, *A. ziphidarum*, *A. nascettii* and *A. typica* (Fig. 3). While the morphotypes indicated as Type II, Type III and Type IV morphology (sensu Berland, 1961; Shiraki, 1974) are corresponding to *A. physeteris*, *A. brevispiculata*, *A. paggiae*, respectively (Murata et al., 2011); these last morphotypes would represent an ancestral character of this group of species (Mattiucci et al., 2018).

Zoonotic role of third-stage larvae of *Anisakis* spp.

The L_3 , known as Type I (sensu Berland, 1961) of the two species *A. simplex* (s.s.) and *A. pegreffii*, are those so far recognized having a zoonotic role to humans. These larval species are most frequently found in the edible parts of commercially important fish and squid species. The musculature as site of infection in the fish can be reached by the L_3 both as an *intra vitam* (for a review, Mattiucci et al., 2018; Levsen et al., 2018) and post mortem event; the last phenomenon has been found to be related to the temperature (Cipriani et al., 2016).

In any case, the ventral flesh (belly flap) of the fish with respect to the dorsal one has been frequently reported as the most infected part of the fish species (Mattiucci et al., 2018) (Fig. 2). As a consequence, those *Anisakis* species are also the species with the highest risk to infect humans. Indeed, live larvae of those two species infecting the fillets of fish and the edible parts of squid to be consumed raw, undercooked, or in various traditional dishes, may cause anisakiasis. Several fish dishes are considered at high risk for consumers to contract anisakiasis. They include, among the others, Spanish boquerones, Italian marinated anchovies, the Scandinavian gravlax, South American ceviche, dutch salted and marinated herring, Japanese sushi and sashimi.

As for the *Anisakis* species included in Clade 2, i.e., *A. ziphidarum* and *A. nascettii* are parasites only rarely found in commercially important fish species and so far the larvae were found on the viscera of the fish rather than the flesh. Further, a higher level of infection was found in deep-sea squid species which, however, are usually not used as “sea-food.” Therefore, it seems that their role in the transmission of the infection to humans is neglectable.

Finally, the larvae of Type I of *A. typica* are only very rarely reported to occur in the fish muscle. Palm et al. (2008) reported the occurrence of one larva of *A. typica* penetrating the muscle of a single fish specimen. Anshary et al. (2014) reported a positive seroprevalence for anisakiasis in humans in Indonesia; however, the etiological agent possibly responsible for that positive serodiagnosis was not identified. No current data exist as regards the occurrence of human anisakiasis from those geographic areas, where *A. typica* has been generally found infecting natural hosts (Fig. 5).

Similarly, no human cases related to the larvae of Type II, Type III and Type IV i.e., *A. physeteris*, *A. brevispiculata* and *A. paggiae* have been so far reported. These species have never been found, to infect the muscle of fish and squids, at least those of commercial importance. Thus, it seems that the risk of infection to humans due to those species could be low. However, Romero et al. (2013) carried out experimental infection of Wistar rats with *Anisakis* larvae, which, according to the authors, were belonging to the species *A. physeteris* and *A. paggiae*. They found, after the necropsy, very few larvae attached to the gastrointestinal wall or penetrating it, thus suggesting that those two species would be able to provoke “invasive anisakiasis” even in humans.

The human disease

Humans become accidental hosts of the L_3 of the parasite species *A. pegreffii* and *A. simplex* (s.s.) by eating parasitized raw or undercooked fish containing viable L_3 of those parasite species in their muscles. These larvae do not mature in humans.

Within few hours of being ingested by humans, L_3 *Anisakis*, alive, penetrates the mucosal layers of both gastric or the intestinal tract, causing direct tissue damage that may lead to the zoonotic disease known as “anisakiasis” or “anisakiosis.” This acute gastrointestinal form of *Anisakis* infection can be transient, with the larval worm also surviving, alive, for some days found trying to penetrate in the submucosa of stomach and intestine (Mattiucci pers. obs.). Clinical symptoms of anisakiasis are not pathognomonic; thus, the acute form could be misdiagnosed. In this case, the infection could become chronic by inducing the formation of

Fig. 5 World map of human anisakiasis, based on the 1960–2020 published literature.

granuloma by the larva. The symptoms could range from nausea to vomiting, from mild to severe abdominal pain, and intestinal obstruction, even mimicking other common gastrointestinal diseases, such as acute appendicitis, peptic ulcer. As a consequence, the anamnestic analysis of the symptomatic patient is mandatory to verify the ingestion of a putative infected raw or improperly treated fish during the previous days before the occurrence of the symptoms. Early removal and identification of the worm seems to be the best preventive measure to avoid the chronic infection evolving in eosinophilic granulomatosis.

Epidemiology of human anisakiasis

Starting with the first case reported from the Netherlands by Van Thiel et al. (1960) and by Smith and Wootten (1978, and ref. therein), human anisakiasis has become increasingly more relevant as human health risk, in particular in countries or regions where the consumption of raw or only lightly processed fish and squid is frequent and/or has become increasingly popular. Consequently, cases of the disease are increasingly reported from Asia (mainly Japan, Korea, China, Taiwan), representing more than 50% of the cases, while the remaining are from European countries, especially Italy, Spain, France and Croatia. While fewer cases are from Germany, Netherlands, United Kingdom and Norway despite comparatively high per capita fish consumption rates in these countries, as well (reviewed in Chai et al., 2005; Audicana and Kennedy, 2008; Bao et al., 2017; Mattiucci et al., 2018; Daschner et al., 2021) (Fig. 5). A number of factors are responsible for the increase of the anisakiasis cases: (i) increased awareness of the disease among physicians, clinicians and biologists; (ii) the improved methods for the detection of the parasites by endoscopy, gastric and intestinal tract, which have facilitated early diagnosis and removal of *Anisakis* spp. larvae; (iii) the molecular identification of the etiological agent; (iv) increased seafood consumption leading to higher per capita fish demand, in parallel with the increased popularity of raw fish.

Most of the human reports (72.0%) describe the occurrence of *Anisakis* spp. larvae associated with gastric anisakiasis (GA), while 26% were invasive and not invasive intestinal cases of anisakiasis (IA), with only 2% being extra-gastrointestinal (Reviewed in Mattiucci et al., 2018).

Actually, the species *A. pegreffii* was reported to cause gastric, intestinal and gastro-allergic anisakiasis (GAA); it was identified in cases of “invasive” anisakiasis, after observing viable larvae during endoscopy (D’Amelio et al., 1999; Umehara et al., 2007; Mattiucci et al., 2013, 2017b; Arai et al., 2014; Lim et al., 2015), colonoscopy (Mattiucci et al., 2017b), or in surgically removed eosinophilic granulomas (Mattiucci et al., 2011, 2017b; Mladineo et al., 2016). Those cases, molecularly identified as caused by *A. pegreffii*, were mostly from Italy (D’Amelio et al., 1999; Mattiucci et al., 2011, 2013), Croatia (Mladineo et al., 2016), from South Korea (Lim et al., 2015) and, more rarely, from Japan (Umehara et al., 2007). These findings are in accordance with the geographic distribution of the parasite species and its infection in those fishes collected within the parasite’s range of distribution.

Anisakis simplex (s.s.) has been identified (by molecular methods) to cause “invasive” gastric and intestinal anisakiasis in Japan (Umeshara et al., 2007; Auer et al., 2007; Arai et al., 2014). But in some European countries, such as Spain, despite widely reported cases of “allergic anisakiasis,” the etiological agent associated with those cases is not being identified at species level by molecular identification (Audicana and Kennedy, 2008 and ref. therein) (Daschner et al., 2021).

It should be underlined that the notification of anisakiasis in humans is not yet mandatory so that, in general, the disease is likely still underreported and misidentified all over the world, especially from those areas where the zoonotic species are widespread (Fig. 5).

Immune response to *Anisakis*

During infection with *Anisakis simplex* (s.l.) larvae, the pathological changes, occurring within the gastrointestinal tract, are the combined result of the direct action of the larva during tissue invasion and the complex interaction between the host immune system and the substances released by, or contained within, the parasite (Audicana and Kennedy, 2008). Indeed, accidentally ingested L₃ of *Anisakis* have to penetrate the gastrointestinal wall, through degradation of the mucosa and submucosa, causing tissue damage and inflammation.

As with other helminth infections, immune responses against internal and cuticular antigens (CE) and excreted/secreted products (ESPs) of *A. simplex* (s.l.) are characterized by an early innate immune response, the first line of defense, rapidly activated, followed by an adaptive immune response, which develops more slowly and provides a tailored response directed against specific antigens (Langrish et al., 2004; Nieuwenhuizen et al., 2013). Innate response against *Anisakis simplex* (s.l.) may involve tissue macrophages, neutrophils, naïve dendritic cells, basophils eosinophils attracted from the chemotactic molecules and cytokines secreted by epithelial cells (Fig. 6).

In the adaptive immune response, through contact with the antigen, the dendritic cells become activated (ADC) and allowing them to act as antigen-presenting cells (APC) after the migration to the adjacent lymph nodes. The recognition of parasitic pathogen-associated molecular patterns (PAMPs) is known to be mediated by certain pattern recognition receptors (PRRs) that are expressed on the APC of the host, so they process and present the antigens to lymphocytes T naïve cells. Napolitano et al. (2018) reported that *Anisakis pegreffii* larvae and their ESPs can inhibit *in vitro* generated DCs, preventing their differentiation and maturation and inducing their apoptosis with a probable immune escape effect.

T naïve cells induce effector cell generation consisting of Th1, Th2, Th17 and T regulatory cells (Treg). In the blood of *Anisakis* spp.-sensitized patients, both Th1 and Th2 cytokines have been recorded (Hrabar et al., 2019). The helminth-induced host immune

Fig. 6 Functional scheme of host defense response against zoonotic species of *Anisakis*. Nitric oxide (NO), excreted/secreted products (ES), macrophages (M^φ), neutrophils (NEU), naïve dendritic cells (NDC), activated dendritic cells (ADC), basophils (BAS), eosinophils (EOS), alternatively activated macrophages (AAM^φ).

response is focused on the protection of the host organism and it is mediated basically by Th2 cells. *A. simplex* induces either a Th1 or a Th2-type immune response, and as this parasite cannot continue its life cycle in humans, it is not possible to determine which type of response could favor the resolution of infection (Nieuwenhuizen, 2016). The alternatively activated macrophages (AAMs), induced by Th2 cytokines such as IL4 and IL-13, are characterized by the production of several enzymes such as arginase-1, which is involved in collagen deposition (Kreider et al., 2007). The activation of AAMs can inhibit the proliferation of other cells like Th1, Th2, and Th17 cells. The Th2 response includes IL-4, IL-5, IL-9, IL-10 and IL-13 secretion, the production of IgG4 and IgE by B cells, as well as the activation of effector cells such as eosinophils, mast cells, and basophils. The Th2 cytokines driving these responses are the same as those that drive allergic diseases and are responsible for the symptoms of Gastro-Allergic Anisakiasis, such as vomiting, itching, angioedema, urticaria and anaphylaxis, as well as *Anisakis* allergy, which can have symptoms such as asthma, rhino-conjunctivitis, urticaria and atopic dermatitis, primarily driven by the mediators released from mast cells. So, after a primary tissue damage (within the first week) marked by edema, massive eosinophil and neutrophil infiltration but also histiocytes or epithelioid histiocytes, lymphocytes, monocytes and plasma cells, of an acute infection, 2 weeks after the infection, a large number of fibroblasts are recruited and deposit connective tissue to form a granuloma and formation of foreign body multinucleated giant cells occurs. Larval remains are broken down and unrecognizable. The generation of T and B cells memory during primary infection sensitizes the host, who may experience allergic reactions upon subsequent exposure to *Anisakis* (Nieuwenhuizen, 2016; Nieuwenhuizen et al., 2013; Caldara et al., 2014).

Molecules involved in the pathogenesis of anisakiasis

The combined result of the direct invasive capacity of the *A. simplex* (s.s.) and *A. pegreffii* larvae and their ESPs and the interaction with the host's immune response during tissue invasion, causes the pathological findings associated with the infection. Although it is likely that the pathogenic effect of the two species is similar, the molecular mechanisms which underlie the human host-parasite species interactions, have not yet been fully elucidated. The "omic" approaches (i.e., transcriptomics and proteomics) of the species of *A. simplex* (s.l.) complex (Baird et al., 2016; Cavallero et al., 2018, 2020; Palomba et al., 2019, 2020a; Łopieńska-Biernat et al., 2020; Stryński et al., 2019; Kochanowski et al., 2020; Marzano et al., 2020; Robertson et al., 2020) has improved the knowledge about some proteins and their transcripts likely having a putative role in the parasite's invasion, infection and allergy.

ESPs are responsible for a multitude of functions during the parasite's infection, such as penetration of host tissues and evasion of host immune responses and, at the same time, are known to elicit immune responses. Therefore, ES proteins are hypothesized to be the major contributors in the clinical manifestation of the disease in humans. Among them, there is ES *Ani s 4* allergen, a cysteine-type endopeptidase with inhibitor activity, present both in excretory glands and below the cuticle. It has been shown that *Ani s 4*, is able to cross the epithelial barrier. These findings could explain the increased intestinal permeability observed in *Anisakis*-IgE sensitized patients (Polimeno et al., 2010; Carballeda-Sangiao et al., 2020).

Proteolytic enzymes, such as peptidases, would be responsible for *Anisakis* pathogenicity likely due to their role in biological pathways linked to the fundamental host-pathogen invasion mechanism of the host tissues. Among the peptidases, the metalloendopeptidase belonging to the Astacin peptidase family and carboxypeptidase were recently identified among the upregulated transcripts in the pharynx of *A. simplex* (s.s.) and *A. pegreffii* (Cavallero et al., 2018). Moreover, high transcripts of metalloendopeptidase were found to be higher in *A. pegreffii* L₃ found in the naturally infected fish musculature compared to the larvae infecting the viscera, enforcing the role of this enzyme as a significant player in host tissues invasion (Palomba et al., 2020a). High transcripts of the gene coding for the Kunitz-type trypsin inhibitor protein (Palomba et al., 2020a) would aid *A. pegreffii* to counteract the host proteolytic enzyme and coagulation factors, as well as high transcripts of hemoglobin. This last protein has been suggested to aid the parasite in maintaining a locally anaerobic environment, while their ability to break down nitric oxide (NO) and hydrogen peroxide produced by innate immune cells which would also help the parasite's survival (Palomba et al., 2020a). The *Anisakis* glycoprotein, GP, which was found highly expressed, would be able to interact with both innate and adaptive branches of the immune system in intermediate and human hosts (Palomba et al., 2020a). Indeed, glycoprotein molecules are involved in the regulation of the IgM response of the intermediate/paratenic fish host (Bahlool et al., 2013).

In order to evaluate molecular markers related to stress response, oxidative stress, inflammation and apoptosis, it was observed that fibroblast cell line HS-68 cells exposed to ESPs and CE products of *A. pegreffii* products led to increased production of reactive oxygen species (ROS) (Messina et al., 2016). In addition, the elevated induction of fibroblasts treated with those products, suggests a significantly negative effect on the human host DNA (Messina et al., 2016). It was also found that *A. simplex* induces an early and reversible alteration of integrity and permeability of epithelial cell monolayer and that an underlying mechanism of this effect would involve the oxidative stress and disruption of the proteins maintaining the barrier function (Carballeda-Sangiao et al., 2020).

It has been also observed that the exposure to *A. pegreffii* CE and ES impaired DC viability, their differentiation and maturation, modulating the ERK1, 2 signaling. These retard DCs at an immature stage, reducing their ability as APCs to trigger an efficacious Th1 response. The interaction between *A. pegreffii* and DC precursors seems to be relevant for inducing a "crippled" immune response, thus suggesting the DC impairment induced by *A. pegreffii* as a possible evasion mechanism of the host immune system, evolved by this parasite (Napoleatano et al., 2018).

It has been also supposed that *Anisakis* CE is able to increase cell proliferation, decreasing apoptosis and inducing changes in the expression of serum cancer-related miRNA in rats. This would envisage a tumorigenic potential for *Anisakis* (Corcuera et al., 2018).

Some of those ESPs of *A. simplex* (s.s.) and *A. pegreffii* are antigenic in the human host immune response, being recognized by specific IgE, IgG and IgG4 in humans and have been so far isolated and characterized (Moneo et al., 2000; Shimakura et al., 2004;

Table 1 Characterized antigens/allergens of *Anisakis* sp. larvae.

Rodríguez-Perez et al., 2008; Caballero et al., 2008; Kobayashi et al., 2011; Daschner et al., 2012) (Table 1). Among them, *A. pegreffii* shows the antigens *A. peg 1*, *A. peg 7* and *A. peg 13*, which are recognized by IgE antibody response in cases of GA or IA (Gonzalez-Fernandez et al., 2015; Mattiucci et al., 2017a; Palomba et al., 2019; de Las Vecillas et al., 2020). Furthermore, parasite' proteins (Table 1) such as *Anis 2* and *Anis 3* are those mainly reported as associated to *Anisakis*-allergic manifestations, such as, for instance, chronic urticaria (CU+) being considered as panallergens (Mattiucci et al., 2017a).

Some *Anisakis* proteins are present in the Allergome database; they have been registered as *Anisakis* allergenic proteins by WHO/IUIS.

Clinical manifestation of anisakiasis

Gastric anisakiasis (GA) and intestinal anisakiasis (IA)

Clinical symptoms of GA as due to *A. simplex* (s.s.) and *A. pegreffii* are similar: epigastric pain, nausea, vomiting, abdominal fullness or distension, anorexia and chest pain (Mattiucci et al., 2013; Guardone et al., 2018). In most of the GA cases, the larvae were mainly located in the lumen of the stomach penetrating the submucosal layer of the gastric wall (Fig. 7). As for the localization in the gastric

Fig. 7 L₃ of *Anisakis pegreffii* in humans provoking: Gastric Anisakiasis (GA) (A–C) with larva extracted by endoscopy (A); and Intestinal Anisakiasis (IA) (D–F) with granuloma formed around L₃ stage, in a transversal (D), and sagittal (E and F) section. *m*, polymyarian muscular cells; *lc*, lateral cords; *i*, intestine; *gec*, glandular excretory cell; *v*, ventriculus; *vij*, ventriculus-intestine oblique junction. D and E: From Moschella CM, Mattiucci S, Mingazzini P, De Angelis G, Assenza M, Lombardo F, Monaco S, Paggi L and Modini C (2004) Intestinal anisakiasis in Italy: Case report. *Journal of Helminthology* **78**: 271–273.

mucosa, the majority of larvae has been reported found in the greater curvature, followed by the posterior wall. Endoscopic findings such as edematous hypertrophic gastric folds, increase in gastric secretion and mucosal lesions, including edema, redness, fibrin deposits, hemorrhage and ulceration have been generally described.

In an experimental model of infection of Wistar rats using the two species, *A. pegreffii* and *A. simplex* (s.s.) (Romero et al., 2013), it was observed that the penetration rate of *A. pegreffii* was lower than that observed for *A. simplex* (s.s.). It could be that *A. simplex* (s.s.) may prefer to invade and penetrate the normal intact gastric mucosa, instead of an atrophic mucosa. This finding can be related to the fact that pH value is lower in the normal mucosa than in atrophic mucosa and that *A. simplex* (s.s.) (Arai et al., 2014) seems to possess a higher penetration rate in agar at low pH (Arizono et al., 2012). In vitro studies have demonstrated that at pH 8.5, proteolytic activity was significantly higher in *A. simplex* (s.s.) than in *A. pegreffii*. At this pH, the majority of activity was due to matrix metalloproteases whose activity was significantly higher in *A. simplex* (s.s.) than in *A. pegreffii*; this phenomenon could be related to the greater invasive capacity of the former species (Molina-Fernández et al., 2019). However, in spite of those findings, it cannot be definitely stated that *A. simplex* (s.s.) is a more pathogenic species with respect to *A. pegreffii*.

Cases of IA due to *A. pegreffii* and *A. simplex* (s.s.) include a “mild form” characterized by eosinophilic granulomas forming “tumor-like” formations in the intestinal wall, and a “fulminant form” with the symptoms of acute ileus, acute appendicitis, acute abdomen or regional ileitis (Fig. 7). Cases of IA reported from Japan, Korea, and Italy (reviewed in Chai et al., 2005; Audicana and Kennedy, 2008; Mattiucci et al., 2018; Guardone et al., 2018), were characterized by a clinical picture of acute appendicitis or acute abdomen. Risk factor differences between human GA and IA have been also observed as regards human anisakiasis, with the male gender in older patients having a major risk of IA (Yamamoto et al., 2020).

Gastro-Allergic-Anisakiasis (GAA)

The term Gastro-allergic Anisakiasis (GAA) (Daschner et al., 2000) indicates an acute allergic reaction in the context of the presence of an alive *Anisakis* sp. larva on the gastric mucosa when attempting to invade the submucosal layer of the stomach wall. GAA is characterized by different manifestations such as urticaria, angioedema and generally consists of an acute IgE-mediated, generalized reaction, starting from few hours to few days after the ingestion of infected fish (Daschner et al., 2011; Mattiucci et al., 2013). Daschner and Pascual (2005) suggested that the allergic reaction following the invasion of an *Anisakis* sp. larva is a protective immunological reaction by the human host to avoid the progressive evolution in the chronic disease, i.e., the granuloma formation.

GAA cases, due to *A. pegreffii*, characterized by urticaria and edema of the oral mucosa, were recognized by molecular methods in patients after they had consumed “marinated anchovies” (Mattiucci et al., 2013). In those cases, endoscope observations showed *Anisakis* larvae invading the submucosa layer of the gastric wall. In addition, serum samples from the patients showed IgE reactivity in western blotting analysis against *A. peg 1*, *A. peg 7* and *A. peg 13* antigenic proteins of *A. pegreffii* (Table 1) (Mattiucci et al., 2017a). In accordance with those findings, *Anisakis* hemoglobin, namely *Anis 13* antigen, was found to induce a strong and prolonged immunoreaction in rats. Similarly, it was shown that *Anis 1* and *Anis 7* antigens/allergens are biomarkers of allergy severity in human anisakiasis (de Las Vecillas et al., 2020).

Anisakis IgE-hypersensitization

Starting since the 1990s, an intense IgE sensitization to *Anisakis* IgE response has been suggested to occur in patients from Japan, Spain, and Italy suffering from GAA, or showing chronic urticaria (CU+) with or without fish consumption. *Anisakis* sensitization can occur by exposure to species-specific allergenic molecules such as *Anis 1*, *Anis 4* and *Anis 7* (de Las Vecillas et al., 2020) or other proteins such as tropomyosin (*Anis 2*) and paramyosin (*Anis 3*), having a strong molecular and immunological cross-reactivity with similar binding proteins from other invertebrates, including crustaceans and dust mites (Mattiucci et al., 2017a; Aibinu et al., 2019). Further, cross-reactive molecules belonging to the SXP/RAL family proteins, similar to those from other nematodes (i.e., *Ascaris*) were identified (Brusca et al., 2020). It has been also reported an “occupational allergy” (dermatitis, asthma, conjunctivitis) caused by *A. simplex* (s.l.) in fishermen and other industry workers (Armentia et al., 1998; Nieuwenhuizen et al., 2006; Jeroncic et al., 2020; Mazzucco et al., 2018). Additionally, it should be taken into account that *Anisakis*-IgE hypersensitivity could vary according to the geographical areas, human populations’ characteristics and genetics, as well the laboratory assays used for its diagnosis (Mattiucci et al., 2018; Daschner and Cuéllar, 2020).

Diagnosis of human anisakiasis

Diagnosis is generally carried out by considering anamnestic data, endoscopy, radiography, serum specific anti-*Anisakis* IgE determination; mast cell degranulation test; the molecular identification of the *Anisakis* larva removed by endoscopy or surgery or expelled by patients is the conclusive assessment. To date, the high number of false positives in the serodiagnosis of *Anisakis*-IgE-hypersensitivity due to cross-reactivity with numerous panallergens have underlined the need to improve the diagnostic approaches.

Histological diagnosis

At the histopathological level, three stages have been defined in the granuloma evolution in both GA and IA, according to Kojima et al. (1996) (Fig. 7). The first stage is recognized as the “phlegmon formation,” and the second one is the “abscess formation.” The last is rather frequent in GA and is characterized by abundant necrotic tissue around the larvae and by a rich population of eosinophils. The third stage is the “abscess-granuloma formation,” which corresponds to the flogistic evolution of the disease from one to several months, after the accidental ingestion of the larva. During the formation of granuloma, the tissue damage created by the *Anisakis*

larva secreting proteins induces chemotactic response for eosinophils and neutrophil recruitment. The larva is then surrounded by eosinophils, neutrophils, lymphocytes and monocytes producing effector molecules possibly capable to kill the parasite. In the meanwhile, fibroblasts are also recruited, which collaborate to the granuloma formation. At this stage, the larva is reduced to few remnants which are invaded by eosinophils, surrounded by giant cells and abundant inflammatory parvicellular infiltrate. Finally, the most advanced stage is that of “granuloma formed” characterized by a further decreased infiltration of eosinophils, but with abundance of lymphocytes, giant cells and significant collagen accumulation (Kikuchi et al., 1990).

When an eosinophilic granuloma has been removed surgically from gastric and intestinal sites, histological preparations (H&E) may reveal relevant features it can reveal the presence of characteristic morphological features of *Anisakis* sp. larvae. In histological transverse sections, the following characters can be noted: a thin cuticle lacking lateral alae; polymyarian muscle cells, separated into four quadrants by chords with two wing-like distal lobes; circular intestine with a triangular lumen and around 50–70 µm tall columnar epithelial cells; banana-shaped excretory cells (renette cells), situated ventrally to the intestine. In the histological sagittal section (Fig. 7), the following features are typical of *Anisakis* sp. larvae: the muscular part of the oesophagus followed by the glandular part (ventriculus) and absence of a ventricular appendix and/or intestinal caecum. However, this can only be achieved when the larva in the nodule is in a good state of preservation. Additionally, those morphological features do not allow identification to species level. This can be, instead, obtained from surgically removed granulomas, by a validated RT-PCR method (Paoletti et al., 2017) which has been proved to be efficient in the identification of the etiological agent, even if the larva in the granuloma is spoiled and/or present at very low quantity (Mattiucci et al., 2017b) (see paragraph below).

Molecular diagnosis

Molecular diagnosis of anisakiasis in humans allows the detection of *Anisakis* DNA in GA and IA cases, by using conventional PCR-DNA direct sequences analysis of target genes (D’Amelio et al., 1999; Fumarola et al., 2009; Umehara et al., 2007; Mattiucci et al., 2011, 2013, 2017b; Mladineo et al., 2016; Kim et al., 2013; Arai et al., 2014). The RT-PCR hydrolysis probe (Mattiucci et al., 2017b) has overcome some limitations related to DNA quantity with respect to the conventional PCR-DNA direct sequencing, allowing the identification of the parasite species even when present in low quantities, in GA and IA cases (Mattiucci et al., 2011, 2017a,b). In the last cases, the etiological agent would have been undetectable as inferred by direct DNA sequencing, due to the low quantity of DNA available.

Serodiagnosis of human anisakiasis and IgE-sensitization

Currently, serodiagnostic tests for *Anisakis* reactivity include the most conventional use of ImmunoCAP (iCAP) assay. However, in recent years other methods have been developed, such as western blotting (WB) and ELISA (reviewed in Mattiucci et al., 2018). Among these, it should especially be noted that specific IgE detection using iCAP assay can overestimate the number of human hypersensitive patients to *Anisakis* allergens. In other words, the sensitivity of these tests can be exaggerated and may yield false-positive results. In recent years, some authors have preferred to use IgE and IgG detection by WB assay, mostly using E/S antigens to differentiate, between GAA and hypersensitive patients (Daschner et al., 2012). Among the antigens related to infection due to *Anisakis*, *Ani s 1*, *Ani s 7* and *Ani s 13* could be considered the major antigens in the diagnosis of anisakiasis (Daschner et al., 2012; Mattiucci et al., 2017b). Nevertheless, the iCAP assay is still used in routine laboratory diagnosis for “*Anisakis*-allergy.” However, some of the apparently positive sera in iCAP assay, can be false-positives, due to: (i) cross-reactive antibodies directed against non-parasitic epitopes; in this case, the iCAP usually shows a pronounced reactivity against panallergenic protein (e.g., tropomyosin); and (ii) an underlying atopic state of the patients who may have some of their polyclonal IgE (Mattiucci et al., 2017b).

Treatment

As stated above, the endoscopically removal of larvae in GA and the surgical intervention of granulomas in IA represent a remedy to the disease and its symptoms in humans. However, despite the fact that there is not a large clinical evidence for a significant success of the use of chemical treatment in the clinical manifestation, it should be mentioned that the use of Albendazole, Prednisolone and Olopatadine hydrochloride have found to improve symptoms in cases of IA (Toyoda and Tanaka, 2016). Furthermore, treatment with corticosteroid and an anti-allergic agent could be an option for patients with IA and GA (Toyoda and Tanaka, 2016).

Preventive measures for raw fish treatment before its human consumption includes deep-freezing at –20 °C for at least 24–48 h, following the Reg. UE n. 853/2004, Annex III, Chapter III).

Conclusion

The disease provoked by *Anisakis* seems to represent in humans an emerging infectious disease where the culinary preference of raw fish consumption is widespread. Not all the species of the genus *Anisakis* are zoonotic; however, data on the fish muscle infection by other *Anisakis* species (i.e., *A. berlandi*, *A. typica*) have been not yet fully investigated. Reports of allergic features associated with the zoonotic species of *Anisakis* are expected to increase in the next decades. In this contest, research aimed to investigate the immunoregulatory features of molecules derived from those parasite species, even to distinguish between a true “*Anisakis*-induced allergy” from “Food allergy.”

Taxonomy, morphology, and life cycle

Blastocystis has a complicated taxonomic history. It was described by Alexieff (1911) and despite the efforts of numerous researchers there are still many unknowns surrounding this organism. It has been viewed as a fungus, a sporozoan and even the cyst of another organism until 25 years ago (Silberman et al., 1996) when it was placed among the Stramenopiles, which is a heterogeneous group of eukaryotes (Adl et al., 2019). The classification of *Blastocystis* was complicated and for so long controversial due to its anaerobic nature and the lack of flagella. Moreover, it is the only human enteric organism within this subgroup, while most of Stramenopiles are free-living and aerobes (Denoeud et al., 2011).

The typical morphology of *Blastocystis* is the spherical “vacuolar” form, ranging in size from 5 to 40 µm (usual range in human stool, 8–10 µm), comprising a large central vacuole with the cytoplasm containing multiple nuclei and mitochondria-like organelles pushed to the periphery (Tan, 2008) (Fig. 1). Moreover, further morphologies have been described such as the granular, the ameboid, and the cystic form. Avacuolar and multivacuolar forms have also been reported, but the vacuolar and the granular ones are the more commonly described in fecal samples and cultures (Tan, 2008).

Blastocystis is characterized by the presence of mitochondria-like organelles (MLOs) (Nasirudeen and Tan, 2004) (Fig. 2), which, like mitochondria, are limited by a double membrane. Sequencing of the complete circular DNA in the MLOs of these parasites by different authors (Pérez-Brocal and Clark, 2008; Wawrzyniak et al., 2008) have showed that the cellular compartments have the metabolic properties of both aerobic and anaerobic mitochondria.

The life-cycle of *Blastocystis* remains incompletely known. Experimental infectivity studies in animals have demonstrated that the water-resistant and environmentally resistant infective cysts are the transmission stage (Suresh et al., 1993; Yoshikawa et al., 2004). Upon ingestion, excystment takes place in the host intestine, giving rise to vacuolar forms. These forms divide by binary fission and may develop further into amoeboid or granular forms. Later, encystment may occur during passage down the colon before cyst excretion in the feces (Tan, 2008).

Molecular characterization of *Blastocystis* subtypes and host specificity

Molecular studies based on the small subunit rRNA gene (SSU-rDNA) have allowed the identification in mammalian and avian hosts of at possibly 22 distinct ribosomal lineages, termed subtypes (STs), which could be considered separate species (Stensvold and Clark, 2020).

A minimum of 5% sequence divergence from the SSU-rDNA is the recommendation for establishing new subtypes, but some (e.g. ST6 and ST9) with respect to other STs, have less than 5% divergence (Stensvold and Clark, 2016).

Several surveys conducted to evaluate the potential risk of zoonotic transmission of *Blastocystis* detected the protist in a wide range of animal hosts, including non-human primates and other mammals such as artiodactyls, perissodactyls, proboscideans, rodents, and marsupials, as well as birds, reptiles, amphibians, fish, annelids, and insects (Yoshikawa et al., 2016; Cian et al., 2017).

Among the 22 *Blastocystis* ribosomal lineages, 10 subtypes have been so far identified in humans. In detail, STs 1–4 are frequently found in humans (Alfellani et al., 2013a), but they have also been detected in hoofed mammals, primates, pigs, cattle, rodents and even birds (Alfellani et al., 2013b). Conversely, STs 5–8 are rarely reported in humans and more commonly found in animals. For instance, ST5 is detected typically in hoofed animals, ST6 and ST7 in birds, and ST8 in non-human primates. When detected in humans, it has been suggested that these subtypes are of zoonotic origin. For instance, ST5 is prevalent in piggery workers in

Fig. 2 Vacuolar form of an *in-vitro* cultivated *Blastocystis* as viewed by transmission electron microscopy (a). This form is spherical with a large central vacuole (v) and a thin peripheral band of cytoplasm (c) around the vacuole. (b) The cytoplasm contains nuclei (n) and mitochondrion-like organelles (m). (c) *Blastocystis* is surrounded by a surface coat (sc). Bars, 2 μ m for (a) and 500 nm for (b) and (c). From Wawrzyniak I, Poirier P, Viscogliosi E, Dionigia M, Texier C, Delbac F, and Alaoui HE (2013) *Blastocystis*, an unrecognized parasite: An overview of pathogenesis and diagnosis. *Therapeutic Advances in Infectious Disease* 1(5): 167–178.

Australia (Wang et al., 2014a), ST6 is frequently isolated from poultry and slaughterhouse staff (Greige et al., 2018) while ST8 has been frequently found in zookeepers who work with non-human primates (Alfellani et al., 2013c). ST9 is the only subtype found in humans today, and even rarely so (Stensvold and Clark, 2016). ST12 was found in humans ($n = 3$) in a study by Ramírez et al. (2016).

The subtype distribution in animals had been investigated in several surveys conducted in animal groups mainly from zoological gardens (Abe et al., 2002; Stensvold et al., 2009a; Alfellani et al., 2013a,c; Cian et al., 2017), national parks (Petrášová et al., 2011), and farms (Wang et al., 2014a) or studies focusing on specific populations (Spanakos et al., 2011; Ruaux and Stang, 2014; Gazzonis et al., 2019; Jiménez et al., 2019).

In general, a large predominance of ST1 to ST3 was identified in primates in Europe (Cian et al., 2017) while in South America monkeys were frequently infected by ST4 and ST8 (Jiménez et al., 2019).

Regarding artiodactyls, Bovidae were mainly positive with *Blastocystis* ST5, ST10 and ST14 while Suidae were shown to be frequently infected by ST5. Birds usually harbor ST6 and ST7, which are considered “avian STs” because of their predominance in this host group (Cian et al., 2017).

Carnivores such as dogs and foxes were not infected by *Blastocystis* (Abe et al., 2002; Spanakos et al., 2011; Paulos et al., 2018) or infected with a low or moderate prevalence (Calero-Bernal et al., 2020), with the exception of stray or sheltered dogs, which showed higher prevalence values (Ruaux and Stang, 2014; Gazzonis et al., 2019).

Potential additional STs were also proposed in non-mammalian and avian hosts including amphibians, reptiles, and insects by Yoshikawa et al. (2016).

In general, most of the vertebrate hosts harbor a single subtype. Mixed infections (i.e. infections by at least two different STs) could result from multiple sources of *Blastocystis*. The prevalence of mixed infections is similar in different countries and roughly ranges between 2.6% and 14.3%. However, their true distribution remains difficult to ascertain and is likely underestimated as it depends on the molecular method employed for subtyping (Meloni et al., 2012).

Studies on the distribution of STs in human populations have revealed geographic variation in the prevalence of STs, which might reflect different epidemiological and demographic characteristics including climate, geography, cultural habits, exposure to reservoir hosts, and mode of transmission (Alfellani et al., 2013a). In general ST3 is the most widespread subtypes followed by ST1 and ST2. The subtype ST4 is the second most common ST in the United Kingdom and it is generally found across Europe but it is less frequently detected or absent in the Far East, South America and Africa. The subtype 5–9 were detected with low frequency in all the major geographic regions (Fig. 3).

However, as the molecular identification of *Blastocystis* was not yet performed from many countries, this epidemiological scenario could change.

Blastocystis genomics

Despite the unanswered questions regarding its potential clinical relevance, studies of complete genomes of *Blastocystis* STs are still scant. Currently, nuclear genomes sequenced so far belong to ST1 (Gentekaki et al., 2017), ST4 (Wawrzyniak et al., 2015), and ST7 (Denoëud et al., 2011).

The ST7 *Blastocystis* nuclear genome, obtained using a culture established from stool of a symptomatic human, was the first complete nuclear genome to be sequenced (Denoëud et al., 2011). The study reported a genome size of 18.8 Mb with 6020 protein-coding genes, which in part appear to have been acquired by horizontal gene transfer. Introns are numerous and small, but elements of repetitive DNA are rare. Individual ribosomal RNA cistrons are sometimes present in sub-telomeric regions of the genome rather than being exclusively found in long tandem arrays as in many other eukaryotes.

Fig. 3 Distribution of *Blastocystis* STs in humans from major geographic regions. Data modified and updated from Alfellani MA, Stensvold CR, Vidal-Lapiedra A, Onuoha ES, Fagbenro-Beyioku AF, and Clark CG (2013) Variable geographic distribution of *Blastocystis* subtypes and its potential implications. *Acta Tropica* 126(1): 11–18.

The ST4 genome was obtained from a laboratory rodent (Wawrzyniak et al., 2015); its size was 12.91 Mb and a set of 5713 protein-coding genes was predicted. There were no detailed analyses of the genome structure or of the genes themselves. The study of the whole genome from these two STs (subtypes 4 and 7) revealed protein-coding genes (aspartic, cysteine, metallopeptidases, serine and threonine proteases) suggesting their role as virulence factors (Gentekaki et al., 2017).

Recently the ST1 genome sequence was also described, highlighting an extreme genomic diversity between the subtypes (Gentekaki et al., 2017). Indeed, ST1 has 6544 protein-coding genes, which is several hundred more than reported for ST4 and ST7. The percentage of proteins unique to each ST ranges from 6.2% to 20.5%, greatly exceeding the differences observed within parasitic protistan genera. Orthologous proteins also display extreme divergence in amino acid sequence identity between STs (i.e. 59–61% median identity), on par with observations of the most distantly related species pairs of parasite genera. The STs also display substantial variation in gene family distributions and sizes, especially for protein kinase and protease gene families, which could reflect differences in pathogenetic potential. As many as 26% of the genes in ST1 have stop codons that are created on the mRNA level by a novel polyadenylation mechanism found only in *Blastocystis*. Reconstructions of pathways and organellar systems revealed that ST1 has a relatively complete membrane-trafficking system and a near-complete meiotic toolkit, possibly indicating a sexual cycle. Unlike some intestinal protistan parasites, *Blastocystis* ST1 has near-complete *de novo* pyrimidine, purine, and thiamine biosynthesis pathways and is unique amongst studied stramenopiles by being able to metabolize α -glucans rather than β -glucans. It lacks all genes encoding heme-containing cytochrome P450 proteins.

However, in addition to the nuclear genome, *Blastocystis* also has mitochondrion-like organelles (Fig. 2), which contain their organellar genome. Indeed, based on staining properties, it was known for many years that these organelles contained DNA, but it was not until 2007 that the coding potential of these molecules was uncovered. Two groups published sequences of the genomes present in the mitochondrion-like organelle in the subtypes ST1, 4 and 7 (Pérez-Brocal and Clark, 2008; Wawrzyniak et al., 2008). The gene content and gene order of the 27–29 kilobasepair circular molecules was identical, although the sequence divergence was considerable. Predictions of the MLO proteome from ST1 has revealed an expanded repertoire of functions, including lipid, cofactor, and vitamin biosynthesis, as well as proteins that may be involved in regulating mitochondrial morphology and MLO/endoplasmic reticulum interactions (Gentekaki et al., 2017).

Subsequently, mitochondrion-like organelle genomes from additional subtypes have been obtained (Jacob et al., 2016). The gene content of the genome of the *Blastocystis* mitochondrion-like organelle is distinct from the more familiar ones from mammals and yeast. Of particular note is the absence of any genes encoding cytochrome and ATPase subunits and the presence of a number of genes encoding ribosomal proteins. In common are the genes encoding ribosomal RNAs and several tRNAs plus NADH dehydrogenase (Complex I) subunits. The nuclear genomes and expressed sequence tag (EST) surveys that are available confirm that the *Blastocystis* mitochondrion-like organelle has only retained complexes I and II of the electron transport chain, a characteristic shared with certain other anaerobic eukaryotes. However, many other features of mitochondrial metabolism are also present (Denoëud et al., 2011). This is in contrast to, for example, *Giardia* and *Entamoeba*, where the mitochondrial genome has been lost completely, and the function of the resulting organelles has become highly reduced. Whether the *Blastocystis* organelle would follow a similar path given enough time is impossible to predict (Pérez-Brocal and Clark, 2008).

Diagnosis

The most common approach to detecting *Blastocystis* is direct microscopic examination of fecal material, with or without addition of Lugol's solution (Suresh and Smith, 2004). Permanent smears stained with trichrome, iron hematoxylin, Giemsa, Gram and Wright's stains have also been recommended (Stenzel and Boreham, 1996). Concentration methods such as zinc sulfate flotation or gravity sedimentation technique are unsuitable for the detection of *Blastocystis* because water, as well as several other solutions, can lyse the non-cyst forms of the protist (Stenzel and Boreham, 1996). Despite the use of microscopy for routine diagnosis of *Blastocystis*, it continues to be one of the more difficult enteric organisms to identify in clinical samples based on morphology. Challenges in its detection pertain to its small size, the occurrence of different forms (especially the difficult-to-recognize cystic form), its degradation caused by environmental conditions or drug treatment, or its occurrence in small numbers. Moreover, vegetative stages can be mistaken for fat globules, other contaminants, or yeast in the stool. *In vitro* culture may help overcome these problems by amplifying the protist number and making them more conspicuous. Other benefits include the possibility of maintaining and expanding isolates of *Blastocystis* in culture for further studies or for their cryopreservation. Various media are available for cultivating of *Blastocystis* such as Locke-egg medium, Iscove's modified Dulbecco's medium, Robinson's medium, TYSGM-9, and Jones' medium. The differences in composition among media suited for growing *Blastocystis*, and the protocols applied for its cultivation, may contribute to variation in sensitivity and specificity of the culture technique (Clark and Stensvold, 2016).

Moreover, culturing the protist may be time consuming and can bias subsequent genotyping due to the differential ability of isolates to grow in selective medium (Roberts et al., 2011). Therefore, to overcome these limitations, several PCR-based diagnostic protocols using DNA extracted from feces directly or after culture of fecal specimens, have been described (Santín et al., 2011; Abe et al., 2003; Scicluna et al., 2006). The SSU rDNA is the marker most frequently used followed by sequencing (Scicluna et al., 2006), which allows identification and analysis of ST genetic diversity. Recently, highly sensitive real-time quantitative PCR assays have been developed to detect and identify *Blastocystis* STs in stool samples by using specific probes or melting curve analysis (Jones et al., 2008; Poirier et al., 2011; Stensvold et al., 2012b).

Immunological approaches are not commonly used in the diagnosis of *Blastocystis*, although the usefulness of a commercially available immunofluorescence assay (Blasto-Fluor, Antibodies Inc.) and ELISA (CoproELISA™ *Blastocystis*, Savyon Diagnostics) were recently evaluated against standard methods for the detection of *Blastocystis* in stool samples (Dogruman-Al et al., 2010, 2015).

Clinical presentation

Blastocystis can be found in both symptomatic and asymptomatic patients (Eroglu et al., 2009). This has stimulated debate in the literature as to whether this microorganism is a pathogen or a commensal—or both.

Typically, *Blastocystis* has not been found to cause macroscopic changes in gut mucosa at upper or lower endoscopy (Zuckerman et al., 1994) although case reports exist where children with high burden of *Blastocystis* in the stools have presented with an acute abdomen suggestive of mucosal invasion and irritation of the peritoneal surface of the bowel (Andiran et al., 2006). Studies conducted in naturally infected pigs evidenced *Blastocystis* primarily in the lumen usually associated with digested food debris, sometimes in close proximity or appearing to adhere to the epithelium, but no stages were found to penetrate the epithelium or the lamina propria (Fayer et al., 2014).

In this context, there is not yet a consensus about the term to describe the host-protist interaction, which could be considered an “infection” or a “colonization”.

Anyway, blastocystosis, i.e. to simplify the presence of *Blastocystis* in the gut, is associated with a variety of non-specific gastrointestinal symptoms e.g. diarrhea, abdominal pain, flatulence, nausea, vomiting, constipation, weight loss or fatigue (Wawrzyniak et al., 2013). Furthermore, it has also been linked to cutaneous disorders and chronic or acute urticaria (Bahrami et al., 2020).

Several studies linked the severity of disease with the protist density. The presence of greater than five cysts per high-power field ($\times 400$) for wet mounts or under oil immersion ($\times 1000$) in permanent-stained smears was frequently associated with an acute presentation of gastrointestinal symptoms (Moghaddam et al., 2005). On the other hand, it has been also suggested that the illness could be related to the different STs (zoonotic or not) involved, to the impact of the protist on the gut microbiota (Andersen et al., 2015) or to the synergic effect of more factors (see the section “Pathogenetic mechanisms”).

Blastocystis was suspected to be involved in irritable bowel syndrome (IBS) (Tan et al., 2010; Poirier et al., 2012; Scanlan, 2012) as a higher prevalence of the protist, in particular of *Blastocystis*-ST1 and ST3, was reported in patients with IBS compared with healthy populations (Yakoob et al., 2010; Jimenez-Gonzalez et al., 2012). However, these studies did not conclude that *Blastocystis* was the sole etiologic agent. Conversely, recent studies demonstrated that *Blastocystis* was more common in healthy individuals than in patients with IBS (Krogsgaard et al., 2015) and, especially, with inflammatory bowel disease (IBD) (Petersen et al., 2013). Furthermore, studies showing the concomitant eradication of *Blastocystis* with the disappearance of symptoms in patients with IBS are needed to clarify this critical issue.

As for as extraintestinal symptoms linked to *Blastocystis*, including arthritis or skin disorders, like urticaria (Bahrami et al., 2020), it has been suggested that the amoeboid form adheres efficiently to the intestinal epithelium, affecting gut immune homeostasis and causing an inflammatory response against the parasite that leads to urticaria (Valsecchi et al., 2004).

In addition, a possible link between *Blastocystis* and allergic disorders was found, but few studies have been so far conducted to elucidate the immunological pathways and antigens that act as allergens. Just one study proposed that the protist induces allergy by increasing complement 3 serum levels in a ST-dependent manner, this being higher in ST3 with a wide absorption of intestinal allergens that indirectly elevate IgE serum levels (El Saftawy et al., 2019). Be careful on this article, probably *Blastocystis* molecules could trigger mast cells in an IgE-independent way.

Furthermore, although the protist was never considered as an opportunistic organism, it has also been frequently found in immunocompromised individuals presenting diarrhea, with prevalence ranging from 15% to 72.4% (Tan et al., 2009; Fontanelli Sulekova et al., 2019), and in patients with HIV/AIDS or cancer (Kurniawan et al., 2009; Tan et al., 2010).

Children from low income countries are also more susceptible due to their socioeconomic status, the quality of drinking water, the consumption of contaminated food and personal hygiene habits (Abdulsalam et al., 2012; Daryani et al., 2012). Also, people in close contact with animals are considered at risk of *Blastocystis*, emphasizing the potentially zoonotic nature of the protist (Yoshikawa et al., 2009; Parkar et al., 2010).

Pathogenic mechanisms

The pathogenic potential of *Blastocystis* remains a controversial issue, primarily due to (i) the high prevalence of asymptomatic carriers (as detailed in the previous section), (ii) the lack of remarkable phenotypic virulence properties showed by the protist relative to other pathogenic protozoa, such as the presence of flagella, lectins, or rhoptries etc., and (iii) the evidence suggesting its pathogenicity has been supposed mainly from *in vitro* models while few experiments have been so far conducted *in vivo*.

However, studies involving co-culture of intestinal epithelial cells with *Blastocystis*, either lysate or excretory/secretory products, in culture filtrates have led to the identification of several potential pathogenic mechanisms (Fig. 4). These include apoptosis (Puthia et al., 2006), the degradation of tight junction proteins resulting in increased intestinal permeability (Mirza et al., 2012), the

Fig. 4 Pathogenic mechanisms of *Blastocystis* described in *in vitro* cultures. From Stensvold CR, Tan K, and Clark CG (2020). *Blastocystis*. *Trends in Parasitology* 36(3): 315–316.

induction of pro-inflammatory cytokines (Puthia et al., 2008), and downregulation of iNOS (Mirza et al., 2011a). In addition, a central role for cysteine proteases in virulence of *Blastocystis* has been demonstrated (Puthia et al., 2008; Nourrisson et al., 2016).

In detail, studies involving co-culture of human colon epithelial cell-line Caco-2 with axenic ST4 and ST7 isolates demonstrated a ST-dependent induction of apoptosis by ST7 mediated by caspase 3 and caspase 9. This effect was not observed in Caco-2 cells infected with the ST4 isolate (Wu et al., 2014). Earlier studies on non-transformed rat intestinal epithelial cells showed that both live protist isolates and lysate of ST4 increased intestinal permeability in a time-dependent manner (Puthia et al., 2006). This study also showed that treatment with lysate and live cells resulted in F-actin disruption and formation of actin stress fibers. In Caco-2 cells, ST7 isolates (both live cells and lysate) were also found to mediate an increase in intestinal permeability in a time- and dose-dependent manner (Mirza et al., 2011a). *In silico* analysis of the *Blastocystis* ST7 genome revealed the presence of a large number of secreted proteases, including 29 cysteine proteases (Denoeud et al., 2011). Among these, a legumain and a cathepsin B, might play a role in pathogenesis of *Blastocystis* by increasing intestinal cell permeability (Nourrisson et al., 2016).

It has been suggested that cysteine proteases of *Blastocystis* induce rho kinase (ROCK)-dependent disruption of intestinal epithelial barrier function with reorganization of cytoskeletal F-actin and tight junctional ZO-1 (Mirza et al., 2012). Caspase 3- and 9-dependent enterocyte apoptosis could also play a role in *Blastocystis*-mediated epithelial barrier compromise (Wu et al., 2014).

In addition to the direct effects on the host intestinal epithelium, *Blastocystis* might also have immunomodulatory properties. Indeed, *Blastocystis* cysteine proteases in lysates as well as in conditioned medium are able to downregulate the product of humoral response by cleaving human secretory immunoglobulin A in a pH- and time-dependent manner (Puthia et al., 2005). Protease activity was found to peak at 24–48 h following culture and also showed inter-subtype variation with higher levels observed in ST7 than ST4 (Mirza and Tan, 2009).

As a pro-survival mechanism, metronidazole-resistant isolates highly susceptible to nitrosative stress were able to avoid cell death by downregulating the expression of iNOS in intestinal epithelial cells, even in the presence of pro-inflammatory cytokines and also by increasing the uptake of arginine (Mirza et al., 2011a). Cysteine proteases from ST4 isolates have been found to induce NFκB-mediated upregulation of IL-8 in human intestinal epithelial cells (Puthia et al., 2008). In murine macrophages, both live isolates and lysates induced MAP kinase mediated upregulation of IL-1β, IL-6 and TNF-α. Serine proteases in ST7 lysate were found to act through ERK and JNK pathways while cysteine proteases were able to induce these pro-inflammatory cytokines in a MAP kinase independent pathway (Lim et al., 2014).

Moreover, clinical studies reported some isolates of *Blastocystis* associated with IBS showed a resistance to metronidazole due to a decrease in cellular immune function (Mirza et al., 2011b). Low levels of CD3+, CD4+, and CD4+/CD8+ ratio counts were observed in *Blastocystis*-carriers compared with non-carriers (Wang et al., 2002). A similar study showed that dysregulation in inflammatory cytokine production (IL-12, IL-10, and TNF-α, IL-8) in colonic mucosa was associated with *Blastocystis* carriage in IBS patients (Yakoob et al., 2014).

In addition to *in vitro* investigations, recent studies have been carried out on laboratory animals including rats, mice, guinea pigs and chickens to understand and confirm the virulence factors of *Blastocystis* using *in vivo* models. During the course of infection, the presence of inflammatory infiltrates in the sub-mucosa (lymphocytic and eosinophilic), mucosal sloughing, and edematous lamina propria have been observed (Abou El Naga and Negm, 2001). Severity of inflammation has been associated with intensity of infection and subtype. Rats infected with ST1 showed more severe pathology while those infected with ST2 (Hussein et al., 2008). In another study, unlike *in vitro* studies, histological examination revealed neither mucosal sloughing nor inflammatory cell infiltration but showed a slight but significant increase in goblet cell numbers in the cecal mucosa 1–3 weeks post-infection with

Blastocystis laboratory strain RN94-9, assigned to ST4 (Iguchi et al., 2009). Upregulation of pro-inflammatory cytokines in intestinal tissue such as IFN, IL-12, and TNF- α , was also reported, suggesting that *Blastocystis* strain RN94-9 is a weakly pathogenic organism that could elicit pro-inflammatory as well as protective responses in local tissues (Iguchi et al., 2009).

Studies on serological response to *Blastocystis* in animal models have been limited with one study describing elevation of anti-IgM and IgG in serum and anti-IgA in intestinal secretions (Santos and Rivera, 2009). A range of potentially immunodominant proteins were identified in western blots arranged with protist lysates but they remain to be further characterized. In pigs, fecal IgA response was demonstrated in ~80% of naturally infected pigs. In addition, an increased response to a high molecular weight antigen (250 kDa) was seen among piglets and pigs that had been immunosuppressed (Wang et al., 2014b).

In addition to the potential virulence factors mentioned, it has been proposed that pathogenicity could be related to genetic differences on the subtype- or strain-level, correlating the ST-1, 4, and ST-7 with pathological alterations in humans, while ST2 and ST3 has been identified as “non-pathogenic” STs (Stensvold et al., 2009b; Eroglu et al., 2009). Also, the presence of both pathogenic and non-pathogenic strains within one subtype has been reported (Hussein et al., 2008). A recent multi-locus sequence typing analysis of *Blastocystis* ST3 and ST4 has provided valuable insight into genetic variation within and between the two subtypes, showing high or low level of genetic diversity for ST3 and ST4, respectively (Stensvold et al., 2012a; Mattiucci et al., 2016). In the latter study, an intra-subtype variability was further evidenced as three haplotypes (H1, H3, H7) were identified in ST3 isolates, while a single haplotype (H2) was observed in ST4 symptomatic patients (Fig. 5), suggesting that the intra-subtype diversity showed by ST3 and ST4 could be linked to the evolutionary history of *Blastocystis* subtypes and ST3 may have co-evolved with human hosts over a longer period than ST4, which may have extended its range to humans more recently.

Impact of *Blastocystis* on the gut microbiota

Over the past few years, several authors linked the impact of the protist on the gut microbiota with its pathogenetic role. Analysis of the microbial communities in healthy individuals or affected by intestinal disorders evidenced three main microbiota patterns, named enterotypes, characterized by three dominant bacteria clusters: *Bacteroides* (enterotype I), *Prevotella* (enterotype II), and *Ruminococcus* (enterotype III) (Arumugam et al., 2011). Each enterotype harbors different bacteria genera, defines a distinctive way of generating energy, and appear to be linked to dietary habits (Rinninella et al., 2019). Next generation sequencing (NGS)-based

Fig. 5 Median joining network analysis of the SSU rDNA sequences obtained in *Blastocystis* subtypes detected in Mattiucci et al. (2016). It was estimated using maximum parsimony (MP) analysis as the optional post-processing calculation using Network 4.6.1.3 software (<http://www.fluxus-engineering.com>) with the default settings and assumptions. Each haplogroup represents a distinct subtype to which a different color is given. The number of the haplotype connection represents a single base difference; the missing haplotypes are indicated by black circles. From Mattiucci S, Crisafi B, Gabrielli S, Paoletti M, and Cancrini G (2016) Molecular epidemiology and genetic diversity of *Blastocystis* infection in humans in Italy. *Epidemiology and Infection* 144(3): 635–646.

studies associated *Blastocystis* with higher diversity of gut microbiota, low body mass index (BMI), and the *Ruminococcus* or *Prevotella*-driven enterotype rather than the *Bacteroides*-driven enterotype (Andersen et al., 2015). These findings were validated using a modified real-time quantitative PCR-based analysis platform, termed ‘Gut Low-Density Array’ (GILDA), including *Dientamoeba fragilis* as well as a control parasite (Andersen et al., 2016). The platform was designed for simultaneous analysis of the change in the abundance of 31 different microbial 16S rRNA gene targets in fecal samples obtained from individuals at various points in time. Both *D. fragilis* and *Blastocystis* were studied in relation to the six bacterial taxa such as *Bacteroides*, *Prevotella*, the butyrate-producing clostridial clusters IV and XIVa, the mucin-degrading *Akkermansia muciniphila*, and the indigenous group of *Bifidobacterium*. In this study, it was observed that *Blastocystis*-carriers alone or along with *D. fragilis* typically had gut microbiota characterized by low relative abundances of *Bacteroides* and clostridial cluster XIVa and high levels of *Prevotella*, confirming the colonization with *Blastocystis* being significantly linked to a low relative abundance of *Bacteroides* (Andersen et al., 2016). Further studies have corroborated these observations and evidenced *Blastocystis* associated with a healthy gut microbiota, characterized by an abundance of bacterial species and, in particular, of potentially beneficial species (Audebert et al., 2016; Nieves-Ramírez et al., 2018). In a study comparing the microbiota in individuals affected by pathogenic parasites such as *Giardia*, with commensal parasites such as *Entamoeba coli*, *E. hartmanni* and *E. dispar* and with *Blastocystis*, dysbiosis, as evidenced by a low *Faecalibacterium prausnitzii*–*Escherichia coli* ratio, was identified in individuals with *Giardia*, while those with *Blastocystis* and *Entamoeba* spp. appeared to be characterized by eubiosis, characterized primarily by a high *F. prausnitzii*–*E. coli* ratio (Iebba et al., 2016).

Conversely, Nourrisson and colleagues noted a decrease of fecal microbiota protective bacteria *F. prausnitzii* in *Blastocystis*-colonized individuals and that levels of *Bifidobacterium* were decreased in males with IBS type C (Nourrisson et al., 2016).

Recent investigations in Italy, focused on *Blastocystis* ST3, confirm and support the link between the protist and an eubiotic state showing a higher bacterial diversity in *Blastocystis* ST3 carriers compared with that identified in *Blastocystis*-negative individuals (Gabrielli et al., 2020). Moreover, at the family level, Prevotellaceae, Methanobacteriaceae, Clostridiaceae were also more abundant, whereas Bacteroidaceae were enriched in *Blastocystis*-free subjects (Fig. 6).

Findings from this and previous studies, suggested that specific subtypes of *Blastocystis* might be considered ‘old friends’, as they may be required for intestinal homeostasis and/or play a role as a marker of intestinal homeostasis (Stensvold and van der Giezen, 2018; Mattiucci et al., 2016). This hypothesis, known as “Hygiene hypothesis” (Rook, 2010), based on Darwinian medicine, incorporates the concept of ‘old friends’, which states that that certain parasitic infections regulate intestinal homeostasis. A lack of childhood exposure to these microorganisms and/or parasites may increase the likelihood of autoimmune diseases in predisposed individuals later in life (Scanlan and Stensvold, 2013). This lack of exposure of the immune system to antigens leads to an imbalance in immune response or dysregulation that facilitates the development of chronic inflammatory conditions. This hypothesis has been recently reappraised to incorporate the concept of ‘Old Friends’ (Rook, 2012). The ‘Old Friends’ hypothesis moreover states that our shared co-evolutionary history with microbes has led to a state of host-evolved dependence on this microbiota. This evolved dependence is such that in a host of particular genetic background, the presence of a particular microbial

Fig. 6 Comparisons of the median values of the relative abundance at the level of bacterial family (level 5) for Bacteroidaceae, Prevotellaceae, Methanobacteriaceae, Clostridiaceae, Lachnospiraceae, Veillonellaceae, Erysipelotrichaceae, Pasteurellaceae in *Blastocystis*-carriers and *Blastocystis*-free subjects (orange and blue bars, respectively). The Mann–Whitney test was used to evaluate the differences between the two groups. From Gabrielli S, Furzi F, Fontanelli S, Sulekova L, Taliani G, and Mattiucci S (2020) Occurrence of *Blastocystis*-subtypes in patients from Italy revealed association of ST3 with a healthy gut microbiota. *Parasite Epidemiology and Control* 9: e00134.

community and/or specific components of the microbiota is required to induce and/or maintain normal immunological responses (Bach, 2018).

Having this concept in mind, it has been suggested that certain STs of *Blastocystis* may actually be part of a normal human intestinal microbiota since the protist has been detected in healthy and asymptomatic hosts for extensive periods of time. In this regard, Krogsgaard et al. (2015) suggested that *Blastocystis* contributes to the diversity of microbiota, and their absence could be a potential indicator of intestinal dysbiosis. In order to persist for such an extended period of time, *Blastocystis* must either evade the immune response, or be recognized as a 'friend'. Furthermore, the predominance of ST1–ST3 (the subtypes most commonly associated with humans) in non-human hosts, such as cattle and pigs (Alfellani et al., 2013c), would suggest that these subtypes have shared co-evolutionary history with humans and their closest living relatives. Conversely, ST4, uncommon in non-human primates, is apparently usual in humans in Europe; however, contrary to ST1–ST3, this subtype appears fairly genetically conserved (Stensvold et al., 2012a), indicating a recent entry in the human population. Consequently, the lack of exposure to intestinal helminths in young generations living in industrialized countries, compared with previous generations (which would have been exposed to several helminths during their youth, as is the case in Italy), may negatively affect the development of the immune system, predisposing them to the colonization even by an 'old friend' protist, such as *Blastocystis* ST3 (Mattiucci et al., 2016).

Despite the above described evidences about *Blastocystis* colonization and eubiotic gut, the presence of the protist in fecal samples is still considered an exclusion criterion for fecal microbiota transplantation (FMT), which is now widely accepted as the most effective therapy in the treatment of recurrent *Clostridium difficile* infection (Paramsothy et al., 2015). Now there is also interest in exploring FMT in the treatment of a range of other gastrointestinal and even systemic conditions, including inflammatory bowel diseases, irritable bowel syndrome, and insulin resistance/metabolic syndrome with clinical trials in progress (Paramsothy et al., 2015). Recently the first transmission of *Blastocystis* ST1 and ST3 by fecal microbiota transplantation was evidenced from two donors with prior negative microscopies (Silva et al., 2019). Molecular analyses on stool samples after donation evidenced the two donors as carriers of ST1 and ST3. Such STs were further detected in patients transferred with *Blastocystis*-positive donor feces, which did not report any significant differences in bowel complaints in the first week, after 3 weeks, or in the months following FMT. Moreover the presence of *Blastocystis* didn't have any significant effect on rCDI treatment outcome.

As previously discussed (section "Clinical presentation"), *Blastocystis* is also speculated to be a direct or indirect cause of gastrointestinal disorders such as IBD, but variation in its relative presence (including ST distribution) between case and control groups and between different studies has led to further confusion. Microbial profiling studies on gut microbiota of patients with IBD showed a decrease in strict anaerobic bacteria and a shift toward facultative anaerobes, such as members of the family Enterobacteriaceae, compared with healthy controls, indicating a role for oxygen in intestinal dysbiosis (Ni et al., 2017). Although it was known that oxygen concentrations increase in a disturbed gut ecosystem, the molecular mechanism was only recently elucidated (Byndloss et al., 2017). Indeed, in a healthy gut, bacteria produce butyrate, which is the preferred metabolic substrate used by colonic epithelial cells in mitochondrial β -oxidation producing ATP, resulting in a decrease of available oxygen (Vital et al., 2014). In addition, the produced butyrate is sensed via a human nuclear receptor and subsequently represses the iNOS (Byndloss et al., 2017), which leads to a reduction in nitrate (Lundberg et al., 2008), inducing a decrease in the proliferation of facultative anaerobes (Byndloss et al., 2017). Butyrate is required to activate oxidative metabolism (Donohoe et al., 2012). A shift away, caused by antibiotics for example, from obligate anaerobic bacteria among the Firmicutes and Bacteroides phyla toward members of the Enterobacteriaceae disrupts the host's butyrate-linked control mechanism and represses oxidative metabolism, increasing luminal oxygen in the human gut (Byndloss et al., 2017; Donohoe et al., 2012). This might partly explain why *Blastocystis* is rare in patients with intestinal dysbiosis-linked diseases: *Blastocystis* being a strict anaerobe (Zierdt, 1986), it is expected that its ability to establish or maintain itself in a microaerophilic environment is limited. This mechanism provides also a possible explanation for the negative correlation between *Blastocystis* and Bacteroides, the latter which, unlike the Firmicutes, contributes little to butyrate production in the gut (Vital et al., 2014) and therefore does not provide an environment where *Blastocystis* thrives (Stensvold and van der Giezen, 2018) (Fig. 7).

The association between gut microbiota and *Blastocystis* also provides a possible explanation for some human populations being more susceptible to *Blastocystis* colonization. Indeed, it has also been frequently found in immunocompromised individuals suffering diarrhea, with prevalence ranging from 15% to 72.4% (Tan et al., 2009). In the survey performed by Fontanelli Sulekova et al. (2019), *Blastocystis* was more frequently identified in fecal samples from HIV-positive patients (22%) than in immunocompetent subjects (7%). This was in agreement with findings from previous surveys (Piranshahi et al., 2018; Tan et al., 2009). However, no significant differences in fecal microbiota composition was found between HIV-positive and immunocompetent subjects, despite immunocompromised individuals showing low bacterial variability and burden. Several authors have evaluated the intestinal microbiome in HIV-positive subjects, with somewhat inconsistent or controversial results (Williams et al., 2016). This may be because of small sample sizes, lack of appropriate controls, and/or regional differences in dietary and environmental factors. Regardless, many authors noted a change in the ratio *Bacteroides*:*Prevotella*; this finding may be linked to the antiretroviral therapy (Vesterbacka et al., 2017), and/or to the sexual practice and lifestyle (Noguera-Julian et al., 2016) of the patients.

Fecal samples from HIV-positive patients enrolled in the aforementioned study (Fontanelli Sulekova et al., 2019) exhibited the so-called *Prevotella* enterotype (or enterotype II), which is characteristic of HIV-positive treated patients (Lozupone et al., 2013; Vujkovic-Cvijin et al., 2013) and, as above described, favors *Blastocystis* spp. colonization. Taking these observations into account, it appears that the high prevalence of *Blastocystis* observed in these patients is a consequence of the microbiota composition, probably induced by the antiretroviral therapy, which highly supports the colonization by the protist, rather opportunism by *Blastocystis* (Gabielli et al., 2020).

Fig. 7 Dynamic interplay between gut flora and human colonocytes. From Stensvold CR and van der Giezen M (2018) Associations between gut microbiota and common luminal intestinal parasites. *Trends in Parasitology* 34(5): 369–377.

Moreover, it has been suggested that microbiota composition in *Blastocystis*-carriers may be dependent on the organism's ST and that certain isolates of *Blastocystis*, as the ST7, potentially lead to an imbalance of the gut microbiota (Yason et al., 2019; Tito et al., 2019). *In vivo* and *in vitro* studies showed that *Blastocystis* ST7 exerts a positive effect on the viability of representative gut bacteria except for *Bifidobacterium longum*. Gene expression analysis and flow cytometry indicate that the bacterium may be undergoing oxidative stress in the presence of *Blastocystis*. *In vitro* assays demonstrated that *Blastocystis*-induced host responses are able to decrease *Bifidobacterium* counts. Mice infected with *Blastocystis* also reveal a decrease in the beneficial bacteria *Bifidobacterium* and *Lactobacillus*. Therefore, these results suggest that certain isolates of *Blastocystis* cause changes in microbiota population and exert their pathogenic effects through disruption of the gut microbiota, providing a counterpoint to the increasing reports indicating the commensal nature of this ubiquitous protist (Yason et al., 2019).

Treatment

Because the pathogenesis is controversial and symptoms are self-limiting, treatment might generally be considered only when other pathogens have been excluded (Stensvold et al., 2010). Several trials have been attempted to evaluate the efficacy of different compounds (Kordestani Shargh et al., 2020) but the eradication of *Blastocystis* is difficult and not straightforward to standardize.

In persistent symptomatic cases, metronidazole and cotrimoxazole (TMP/SMX) have often been the drugs of choice, despite the fact that they are not always effective (Stensvold et al., 2010). Other drugs have been trialed with variable success, including iodoquinol, inidazole, nitazoxanide, paromomycin, ketoconazole, and ornidazole (Roberts et al., 2015). It has been speculated that any resolution of symptoms may actually be secondary to eradication of some unrecognized microorganism(s) rather than to be a result of *Blastocystis* eradication (Markell and Udkow, 1986).

However, several factors depending on both protist and host can affect the therapy outcomes and the persistence of *Blastocystis* in the stool. Indeed, while in some cases the infection spontaneously resolves (Nigro et al., 2003; Rossignol et al., 2005), other individuals remain non-responsive to the treatment (Haresh et al., 1999). It has been speculated that treatment failure could reflect the acquisition of drug resistance by *Blastocystis* (Moghaddam et al., 2005); however, genes potentially responsible for activation/inactivation of metronidazole have not so far been identified (Roberts et al., 2014). Indeed, the success of *Blastocystis* elimination also depends on whether sufficient amount of drug can be delivered to the colon (Kumar et al., 2008). Moreover, inactivation of the drug by the normal bacterial flora has been suggested to explain treatment failure with metronidazole since healthy people receiving metronidazole exhibit almost no change in their fecal microbiota profile (Stensvold et al., 2010). Finally, particularly in highly endemic areas, reinfection may occur frequently, which could be interpreted as treatment failure. Here, longitudinal detailed strain characterization could be useful, and the use of highly sensitive and discriminatory molecular diagnostic source and disease-tracking tools are required to provide further insight into reinfection, and transmission dynamics of *Blastocystis* and to clarify the effectiveness of the therapy.

Furthermore, since the link between gut microbiota composition and *Blastocystis* was elucidated, the potential of probiotic bacteria as alternative therapy in *Blastocystis*-carriers was investigated (Dinleyici et al., 2011). Recently, a study aimed to evaluate the efficacy of the lactic acid bacteria *Lactobacillus rhamnosus*, *Lactococcus lactis*, and *Enterococcus faecium* in *Blastocystis*-ST3 eradication and showed the potential of using these bacteria as a prophylactic treatment against *Blastocystis* colonization. The ability of these probiotic bacterial strains to disrupt the cell cycle of *Blastocystis* shows a promising future in the use of probiotics for prophylaxis, or as an additional treatment regimen in combination with standard drugs (Lepczyńska and Dzika, 2019).

Conclusion

Recently, there has been increasing interest by the scientific and medical community in *Blastocystis* coupled with new data on epidemiology, potential pathogenicity, and, more recently, the first whole genome investigation of some *Blastocystis* STs. In 2008 the protist was included in the Water Sanitation and Health programs of the World Health Organization (WHO, 2008). Accumulating *in vivo* and *in vitro* data appear to indicate some importance of *Blastocystis* to human health, but its role in human and non-human disease remain to be identified in greater detail, and the development and standardization of axenization, diagnosis tools, transfection and animal models, microarrays and genotyping markers would be useful in this process. Sequencing of genomes from different STs and comparative genomic projects are in progress in several laboratories and the results will be useful to identify specific virulence factors. Multicenter studies and networking are also required to further our comprehension of the clinical implications of *Blastocystis* in IBS and other conditions. Finally, the interaction of *Blastocystis* with gut microbiota should be studied because of the increasing awareness of the role played by microbiota disturbances in the development of various gastrointestinal dysfunctions.

To conclude, as much remains to be learned about this parasite, a multidisciplinary approach is required to increase our knowledge of key aspects of the *Blastocystis* biology and further our understanding of its clinical relevance and public health significance.

Acknowledgments

The authors would like to thank Dr. Federica Furzi and Dr. Marialetizia Palomba for their contribution during the manuscript preparation.

Introduction

Clonorchis sinensis, *Opisthorchis viverrini* sensu lato (s.l.) and *Opisthorchis felinus* are liver fluke parasites that humans can acquire by consuming raw or partially cooked freshwater fish infected with the larval stage metacercariae.

Besides being the etiological agents of helminthic diseases, *C. sinensis* and *O. viverrini* s.l. have been classified as class I carcinogens, since they are the causative agents of cholangiocarcinoma (CCA) in chronically infected people, whereas *O. felinus* as class III (IARC, 1994; Bouvard et al., 2009). It is estimated that 35 million people are infected with *C. sinensis* mainly in China, 10 million with *O. viverrini* s.l. in Southeast Asia, in Lower Mekong Basin (Thailand, Lao PDR, Cambodia, Myanmar and Southern Vietnam). In Northeastern Thailand the prevalence of human opisthorchiasis (16.6%) is the highest in the world, and it is coincident with the highest incidence of CCA (Sithithaworn et al., 2012; Sripa et al., 2012a). *O. felinus* infects 1.2 million people in Eastern Europe and Russia (WHO, 1995; Sithithaworn et al., 2012; Saijuntha et al., 2021) and some hundreds of cases have been documented in Europe (Pozio et al., 2013). For 2018, an estimated 2.2 million infection-attributable cancer cases were diagnosed worldwide, from them, 3500 new cases of CCA were attributable to *C. sinensis* and *O. viverrini* s.l. infections (De Martel et al., 2020).

Systematics

Clonorchis and *Opisthorchis* belong to the phylum Platyhelminthes, class Trematoda, subclass Digenea, order Plagiorchiida, family Opisthorchiidae (Mordvinov and Furman, 2010). Studies of the population genetic structure of these liver flukes have uncovered sub-structure patterns that are related to geographical isolates in defined catchment/wetland systems (Petney et al., 2018). Molecular genetic investigations of *O. viverrini* in Southeast Asia showed that it is a species complex '*O. viverrini sensu lato*' containing two evolutionary lineages with many cryptic species (morphologically similar but genetically distinct species) occurring in and within different catchment (wetland) systems in Thailand and Lao PDR (Saijuntha et al., 2007; Sithithaworn et al., 2012).

Life cycle

The adult hermaphrodite worms (*C. sinensis*: 10–25 × 3–5 mm; *O. felinus*: 7–12 × 1.5–2.5 mm; *O. viverrini*: 5.5–10 × 0.8–1.6 mm) are dorso-ventrally flattened with an anterior oral sucker, a centrally located ventral sucker, and a uterine pore. The natural life cycle of these trematodes is similar among them and complex (Fig. 1). Freshwater species of snails belonging to the families Assimineidae, Bithyniidae, Hydrobiidae, Melaniidae and Thiaridae are the first intermediate hosts for *C. sinensis* (Lun et al., 2005). *Bithynia funiculata* and two subspecies of *B. siamensis* (*B. siamensis siamensis* and *B. siamensis gomiomphalos*) are the first intermediate host for *O. viverrini* (Petney et al., 2018; Sithithaworn et al., 2012). *O. felinus* has been found in the species *B. inflata*,

(B) Metacercariae of *O. felineus* collected from a tench filet after digestion with 1% pepsin and 1% HCl in tap water. (C) Excystation of an *Opisthorchis felineus* metacercariae after artificial digestion with 1% pepsin and 1% HCl in tap water. Scale bars = 100 μ m. Courtesy of Gianluca Marucci, Department of Infectious Diseases, Istituto Superiore di Sanità, Italy.

B. leachii, and *B. troscheli* (Erhardt et al., 1962; Hering-Hagenbeck and Schuster, 1996; Mordvinov et al., 2012). The second intermediate hosts in which metacercariae develop are freshwater fish, commonly of the Cyprinidae family, however other fish families and crustaceans have been reported to host *C. sinensis* larval stages with high prevalences (Lun et al., 2005). In Europe, *O. felineus* metacercariae have been detected in *Alburnus alburnus*, *Abramis brama*, *A. ballerus*, *Blicca bjoerkna*, *Idus idus*, *Rutilus rutilus*, *Scardinius erythrophthalmus*, and *Tinca tinca* with prevalences up to 95% (De Liberato et al., 2011; Pozio et al., 2013). The most important second intermediate hosts of *O. viverrini* are cyprinoid fish of the genera *Cyclocheilichthys*, *Hampala*, and *Puntius* (Wykoff et al., 1965). The number of metacercariae in fish varies by season, species, and physical and biological parameters of the water bodies (Sithithaworn et al., 2007). The metacercarial burden of *C. sinensis*, *O. felineus*, and *O. viverrini*, peaks in spring and summer, summer and autumn, and winter, respectively (Sithithaworn et al., 2007; De Liberato et al., 2011).

After ingestion of the infected fish, the metacercariae (Fig. 2) excyst in the duodenum of the definitive hosts (mammals) and within 30 min the juvenile flukes migrate up through the Ampulla of Vater and the common bile duct into the intra-hepatic bile ducts where they attach to the bile-duct epithelium using their suckers. Then, flukes develop into adults after at least 1 month (Sripa et al., 2007) and operculate eggs ($22\text{--}35 \times 10\text{--}22 \mu\text{m}$) containing the miracidium, are shed with feces (Fig. 1). An adult worm can produce up to 4000 eggs per day (Wykoff et al., 1965; Fig. 3). Fluke metabolic pathways are highly adapted to a lipid-rich diet from bile and/or cholangiocytes as showed by the studies based on the draft genome and transcriptomes of *O. viverrini* and *C. sinensis* (Wang et al., 2011; Huang et al., 2012; Young et al., 2014). When eggs reach the freshwater and are ingested by the first intermediate host (snails), they hatch in the gastrointestinal tract of the snail, and the miracidium develops into a sporocyst in the intestinal wall or in other organs to undergo asexual reproduction. The sporocyst produces rediae which mature in the hepatopancreas within about 17 days. The cercariae, about 5–50 per redia, leave the snail via the siphon into freshwater during the day, when it is warm and sunny, approximately 1–2 months after the snail is infected; however, the duration of development in the snail body is strongly influenced by the water temperature. The free-swimming cercariae, which are characterized by a positive photo- and geo-tropism, have a long tail with a long dorsal and some shorter ventral fins, a finely spined tegument, penetration and cystogenous glands, and a pair of eyespots (Fig. 1). They shed their tail, penetrate fish tissue between the scales (mainly near the fins), and encyst as metacercariae under the skin or in the musculature approximately 3 weeks later. In doing so, the cercariae lose their eyespots and develop a sac-like excretory bladder filled with coarse, refractile granules. The metacercarial stage is usually ovoid ($140 \times 120 \mu\text{m}$)

Fig. 3 (A) Liver from an *Opisthorchis felineus* infected hamster in which parasites are visible inside the main bile duct (black arrows) and coming out from it (red arrows). (B) *Opisthorchis felineus* adult kept in culture ($12 \times 2.5 \text{ mm}$) once isolated from the liver of an infected hamster. Photographs are at original magnification $10\times$. with a thin wall (Fig. 1). The definitive host acquires the infection by eating fermented, raw or undercooked freshwater cyprinid fish containing the infective metacercaria. In humans, flukes can survive for more than 20 years (Attwood and Chou, 1978; Kaewpitoon et al., 2008).

As an example, the life cycle of *C. sinensis* is shown in Fig. 1.

Pathogenesis

The magnitude of the pathology caused by these parasites depends on their number, duration of the infection and susceptibility of the host. The intrahepatic flukes move up to and clog biliary branches causing a mechanical injury by their feeding and migrating activities, both oral and ventral suckers of the fluke hook up the biliary epithelium. Moreover, the excretory/secretory products (ESPs) released by the parasites induce inflammation and stimulate cell proliferation of the biliary epithelium, causing immunopathological responses (Sripa et al., 2018b).

In light *C. sinensis* human infections, the liver appears normal, in massive infections, a localized dilation of the thickened peripheral bile ducts can be seen on the surface beneath the Glisson's capsule. At late stages of infections, *C. sinensis* adults block the biliary passages and bile flow. The congested bile increases hydrostatic pressure, presses on the ductal wall, and causes dilatation (Na et al., 2020). The damaged tissue present edema followed by tissue desquamation mainly in the areas close to the flukes. At later infection stages, there is epithelial hyperplasia that advances to adenomatous hyperplasia in the biliary epithelium with a high number of goblet cells. In chronic infections, epithelial cells proliferate with metaplasias of the biliary epithelial cells into mucin-producing cells. Goblet cells can proliferate to produce many small gland-like structures in the mucosa (adenomatous hyperplasia), leading to an excessively high mucus content in the bile, which in combination with the presence of eggs and worm fragments, causes cholestasis and serves as support for bacterial superinfection and cholelithiasis (Lim, 2011). Secondary bacterial infections, mainly of enteric origin, may occur, and *Escherichia coli* is the pathogen most frequently identified. These alterations may progress to a pyogenic cholangitis, liver abscess, and hepatitis (Na et al., 2020). Cholecystitis may appear associated to the infection, consequently, a poor function of the gallbladder causes precipitation of bilirubinate, calcium carbonate crystals, and mucin on the eggs, which causes stone formation in the gallbladder that can lead to biliary obstruction (Sithithaworn et al., 2007; Qiao et al., 2014). In severe infections, periductal fibrosis extends up to bile capillaries and down to the portal area. The area around the affected bile duct is infiltrated by lymphocytes, plasma cells and eosinophils. As the fibrosis proceeds, the epithelial proliferation appears milder and fecal egg production drops markedly. In some chronic cases, hepatobiliary fibrosis progresses to cirrhosis (Na et al., 2020). Pancreatitis associated to *C. sinensis* infection have been documented (Kim, 1999). Developmental retardation has been reported in *C. sinensis* infected children with heavy infection. These children often present inappetence, diarrhea, malnutrition, anemia, and hepatomegaly (Zhu et al., 1983).

In *O. viverrini* infections followed by ultrasonography and cholecystography in Northeast Thailand, gall bladder wall irregularity, enlargement, and bile sludge has been reported among apparently healthy individuals with moderate infections (Elkins et al., 1996; Mairiang et al., 1992). In heavy *O. viverrini* infections, the liver may be enlarged, its weight may be more than double the normal (3000–3500 g or more), the predominant changes documented included desquamation of the biliary epithelium, epithelial hyperplasia, bile duct hyperplasia, and periductal fibrosis (Riganti et al., 1989; Sripa et al., 2012a). In the large and medium-size bile ducts, the flukes can cause chronic cholecystitis. In case of a superimposed bacterial infection, empyema of the gall bladder may exist. Cholelithiasis is not particularly frequent in *O. viverrini* infections; however, biliary sludge is often seen in heavy infections. The enlargement of the gall bladder is commonly found in ultrasonographic studies (Mairiang et al., 1992, 2012). In chronic infection, periductal fibrosis developed along the infected bile ducts is the most prominent pathological feature and it is implicated, in its advanced form, i.e., as advanced periductal fibrosis (APF), as one of the risk factors for CCA development (Sripa et al., 2012a). Nonfibrotic presentations, such as gallbladder morphology and function, recover after removal of parasites by drug treatment; however, AFP appears to be permanent (Mairiang et al., 1993). Granulomatous inflammation around the parasite eggs is occasionally seen in the gall bladder wall during infection (Riganti et al., 1989). *O. viverrini* infection modulates the microbiota of the biliary tract since there is a documented increased of microbial diversity in *O. viverrini* associated tissues versus non-*O. viverrini* associated tissues, whether tumoral or normal (Chng et al., 2016).

In *O. felinus* human infections, pathological changes seem to be like those induced by the other liver flukes; however, the information is scarce. In patients with heavy or prolonged infections or superinvasion 84% develop duodenal hypertension, 94% gastric hypertension, and 75% duodenogastric reflux that can lead to chronic gastritis and chronic esophagitis (Suvorov et al., 2004). Moreover, regurgitation of intestinal contents into the pancreatic duct can be cause of chronic indurative pancreatitis of the head of the gland. Sonographic studies carried out in *O. felinus* infected people have evidenced disturbances in the gall bladder ranging from dyskinesia to cholestatic syndrome, mainly in the early phase of the disease (Bronshtein et al., 1989). In a patient who underwent liver biopsy, acute inflammatory signs with dilatation of portal spaces and eosinophilic infiltration with lymphocytes and monocytes, were found (Traverso et al., 2012). *O. felinus* infection may cause complications, such as cholangitis, cholecystitis, cholangiofibrosis, hepatic cysts, hepatic abscesses, and pancreatitis. In studies conducted in Western Siberia (Russia), out of 4756 people chronically infected with *O. felinus*, 1170 (24.6%) required surgical intervention for complications associated to the infection (cited by Pakharukova and Mordvinov, 2016). Renal alterations have been described in human infected with *O. viverrini* (Boonpucknavig and Soontornniyomkij, 2003) and *O. felinus* (Lapteva, 1990). Analyses of microbial communities did not reveal differences in bacterial richness between participants infected with *O. felinus* and noninfected individuals (Saltykova et al., 2016).

From liver fluke infections to cancer

Epidemiological studies revealed that current or past *O. viverrini* and *C. sinensis* infections are the major risk factor of intrahepatic CCA (Honjo et al., 2005; Choi et al., 2006). Moreover, coinfections with other carcinogenic microbes and local and systemic chronic inflammation influence the process (Brindley et al., 2015). However, the highest risk factor is the elevated serological positivity associated to the host genetic polymorphism of glutathione S-transferase mu 1 (GSTM1) gene. Other risk factors have been specified as area of residence, alcohol consumption, age (older than 60), sex (male), smoking and consumption of fermented raw fish (Fried et al., 2011). Sripa and coworkers associated elevated plasma IL-6 with increased risk of advanced fibrosis and cholangiocarcinoma in individuals infected with *O. viverrini* (Sripa et al., 2012b).

Even if the understanding of the mechanisms leading from liver fluke infection to CCA is not complete, the general mechanisms proposed to contribute to CCA through chronic infection include mechanical damages of the parasites, toxic effects of their excretory/secretory products (ESPs) to the biliary epithelia and the immunopathology due to infection-related inflammation.

Differential transcriptional and proteomic profiles in human CCA cells treated with *C. sinensis* ESPs showed upregulation of carcinogenesis and cell proliferation related genes and down regulation for genes related to apoptosis (Pak et al., 2009a,b, 2014; Kim et al., 2010; reviewed by Qian et al., 2016). As *O. viverrini* ESPs, *C. sinensis* ESPs also trigger enzymatic free-radical generation through the activation of TLR isoforms, which in turn lead to NF- κ B-mediated inflammatory processes, inducing the increase in mRNA and protein expression of the pro-inflammatory cytokines IL-1 β and IL-6, suggesting that continuous disruption of host redox homeostasis during liver fluke infection may create an environment for the development of an advanced hepatobiliary disease, including chronic-inflammation-associated CCA (Kim et al., 2012; Nam et al., 2012; Bahk and Pak, 2016; Maeng et al., 2016). Recent studies show that *C. sinensis* ES enhance the activation of hepatic stellate cells (HSC) by a cross-talk of TLR4 and TGF- β /Smads signaling pathway, which turns in secretion of TGF- β 1 from activated HSCs and other cells. TGF- β 1 is an essential mediator of fibrogenesis (Li et al., 2020). These studies indicate that *C. sinensis* ESPs may function as inducers of multiple oncogenic pathways (Pak et al., 2014).

Experimental studies demonstrated that *O. viverrini* ESPs can be internalized into liver cell lines by endocytosis, driving IL-6 secretion and inducing proliferation of liver cells (H69 and CCA lines) but not intestinal (Caco-2) cells (Chaiyadet et al., 2015a). Within *O. viverrini* ESPs, extracellular vesicles (EVs) are released as for communication with neighboring host cells. EVs promote inflammation yet simultaneously act as modulator, since cholangiocyte protein expression (H69) undergoes dysregulation after coculture with EVs (Chaiyadet et al., 2015b). EVs are highly enriched in tetraspanins (TSPs), proteins that interact with transmembrane and cytosolic signaling proteins (Hemler, 2005). Antibodies to a TSP located on the surface of *O. viverrini* EVs blocked the ability of fluke EVs to be internalized by cholangiocytes and suppress the cell proliferation and secretion of IL-6. *O. viverrini* ES products comprise a complex mixture of proteins, some of which have homologs in the human host that are associated with cancer (Mulvenna et al., 2010). Among them, the Ov-GRN-1 (Smout et al., 2009) has a sequence like that of the mammalian growth factor granulins and may mimic the action of IL-33 as epithelial mitogen for cholangiocytes in the development of CCA, priming type 2 innate lymphoid cells to induce proliferation of neighboring cholangiocytes by the release of IL-13 (Li et al., 2014; Sripa et al., 2018a). When internalized by human cholangiocytes, Ov-GRN-1 can induce gene and protein expression changes associated with cancer pathways, as the epithelial mesenchymal transition (EMT) phenotypes (Smout et al., 2015). A glutathione S-transferase (OvGST) has been also identified in ESPs, which had a dose-dependent proliferative effect on murine fibroblasts (NIH-3T3) and on the non-tumorigenic human bile duct epithelial cells MMNK1 cells (Daorueang et al., 2012).

Proteomic identification of the ESPs released by *O. felineus* allowed the identification of 37 proteins, among them, the major component is a glutathione-dependent prostaglandin synthase (Lvova et al., 2014), which seems involved in *O. felineus* pathogenesis, including the precancerous lesions (Pakharukova et al., 2019). Even if no recognized association has been reported for *O. felineus* and CCA, epidemiological and clinical data in humans and animals suggest that *O. felineus* can be the cause of neoplasia. Thus, in Russia, the highest incidence of bile duct cancer in humans was documented in the same area (i.e., Tyumen oblast) with the highest prevalence of *O. felineus* infection in humans (Mordvinov et al., 2012). In Italy, pre or cancerous lesions have been found during autopsy in *O. felineus* naturally infected animals, in particular cats and dogs (Pozio et al., 2013). In addition, there is an increase of experimental data supporting information for a role of *O. felineus* infection as a risk for CCA (Lvova et al., 2012; Maksimova et al., 2017; Kovner et al., 2019).

Clinical manifestations

Most of the reported liver fluke infections are dormant and the infected people are asymptomatic, except for the patients with very heavy infections and for those presenting complications.

Clonorchis sinensis

Patients with mild infections, i.e., with fewer than 100 flukes, have few symptoms as general malaise, abdominal discomfort, and diarrhea. In 10–40% of patients, peripheral eosinophilia accompanies a fluctuating jaundice that is usually obstructive. Moderate infection (generally fewer than 1000 flukes) presents with fever and chills, as well as fatigue, anorexia, diarrhea, weight loss, discomfort, and abdominal distension. Up to 20,000 flukes may be present in patients with severe disease, who present with acute

right upper quadrant pain, often superimposed on the signs and symptoms seen in moderate infections. In the late stage of severe cases, jaundice, diarrhea, ascites, and edema, can occur. Differential diagnoses of clonorchiasis include acute or chronic hepatitis, cancer along the bile ducts, hepatolithiasis with recurrent pyogenic cholangitis, sclerosing cholangitis, Caroli's disease, and *Fasciola hepatica* infection (Choi et al., 2005, 2006; Keiser and Utzinger, 2009).

Opisthorchis viverrini

In patients with a severe infection, the clinical signs and symptoms include lassitude, and nonspecific abdominal complaints such as anorexia, nausea, vomiting, abdominal discomfort, diarrhea, indigestion, weight loss, ascites, and edema (Furst et al., 2012). There is no report of acute *O. viverrini* infections. Most subjects with opisthorchiasis have non-specific symptoms or no symptoms at all. Intrahepatic duct stones and recurrent suppurative cholangitis is not a common manifestation of opisthorchiasis caused by *O. viverrini* but can be present. Obstructive jaundice can be presented alone, with fever, or with acute abdominal complications. Since jaundice is the main clinical manifestation of the CCA, whenever jaundice and ascending cholangitis are detected in endemic areas, the fluke-related CCA is suggested (Uttaravichien et al., 1999). Non-jaundiced patients may present dyspeptic pain, anorexia, weight loss, right upper abdominal mass (Chunlertrith et al., 1992).

Opisthorchis felineus

The clinical manifestations during the acute stages of the infection in humans are characterized by fever, abdominal pain, headache, asthenia, arthralgia, lymphadenopathy, skin rash, diarrhea, nausea, hepatitis-like symptoms, eosinophilia, and increased liver enzymes (Mairiang and Mairiang, 2003; Mairiang, 2017; Mordvinov and Furman, 2010; Traverso et al., 2012; Pozio et al., 2013). These clinical features may lead to misdiagnosis as acute viral hepatitis (Belova et al., 1981) and rheumatic disease (Gordon et al., 1984). Acute opisthorchiasis occurs early in infection and may be associated with primary exposure to a large dose of metacercariae (Furst et al., 2012). In endemic regions such as Ukraine, Russia and Siberia, where people frequently consume raw fish, the number of worms in the bile ducts can be very high, inducing chronic infection, which is characterized by anorexia, dyspepsia, dryness and bitter taste in the mouth, fatigue, intolerance to greasy foods, nausea, and pain in the right hypochondrium (Mordvinov and Furman, 2010). In non-endemic areas, such as EU countries, most infected persons show pauci-symptomatic or asymptomatic forms and in some cases, clinical disease and the seroconversion can develop up to 2 months after infection. In Italy, about 1/3 of infections was asymptomatic (Pozio et al., 2013). In symptomatic persons, during the acute stage, the more frequently observed signs and symptoms were asthenia, headache, abdominal pain, and fever, which started about 2–3 weeks after the infection (Armignacco et al., 2008; Traverso et al., 2012; Pozio et al., 2013). Jaundice was not observed. The main laboratory findings were leukocytosis, eosinophilia, increased transaminases (Armignacco et al., 2008; Traverso et al., 2012). In an outbreak in Italy, in persons not diagnosed during the acute phase and then not treated, there was a spontaneous remission of the clinical symptoms within 2–3 months of infection, although the liver flukes were still present and produced eggs (Armignacco et al., 2013).

Immune response

During infection, liver flukes are exposed to the biliary epithelium and neither mucosal nor tissue immune responses appear to cause parasite death or protect the host against new flukes, as evidenced by the persistence of human infections for decades in the body and rapid reinfection following treatment (Sripa et al., 2018a).

Humans are susceptible to infection, re-infection and superinfection by *C. sinensis* (Hong and Fang, 2012). However, rats, mice, and rabbits resist against re-infection and super-infection of *C. sinensis* (Sohn et al., 2006). Only a few worms survive as small and immature forms in the bile duct of re-infected or super-infected rats; however, the rat resistance has not been observed in immune-suppressed or nude (athymic) rats (Zhang et al., 2008a,b). In FVB mice, which are susceptible to *C. sinensis*, primary infection induced elevated levels of Th2 cytokines (IL-4, IL-5) and by 70-fold increase of Kupffer cells in the liver compared to non-infected controls. These animals were resistant to re-infection and presented an increase of B cells in biliary lymph nodes as well as increased serum levels of *C. sinensis*-specific IgG1 and IgG2a (Kim et al., 2017). Using the same strain of mice, Yu et al., reported an enhanced IgE's binding capacity for B cells after infection, which suggested the roles of IgE as a Th2 response amplifier and its protective role in parasite infection (Yu et al., 2019). These studies are in line with previous investigations, in which specific antibodies to *C. sinensis* were produced in serum and bile of experimentally infected rats, mainly IgE in serum and IgA in bile, and their levels correlated with resistance (Wang et al., 2009; Zhang et al., 2008a,b). Splenectomized rats show resistance to *C. sinensis*, which suggests that the spleen is not a key organ in the development of resistance (Zhang et al., 2008a). Zhao et al., showed that *C. sinensis* adult-derived proteins inhibited LPS-induced maturation of bone marrow-derived dendritic cells and induced the differentiation of naive T cells into Th2 cells though the production of IL-10. They also confirmed in the same study that *C. sinensis* proteins initiated Th2-cell skewing immune responses to markedly elevate the production of IL-13 and IL-4, which are closely associated with the generation of liver fibrosis (Zhao et al., 2018). Previously, Zhang and colleagues reported an association between increased hepatic Th2 and Treg cell subsets and biliary fibrosis in *C. sinensis*-infected mice (Zhang et al., 2017).

O. viverrini induces a strong antibody response in the human host, with IgG being the predominant subclass followed by IgA and IgE. The specific immune response is detectable in serum and bile, and it comes along with a marked increase of total IgE in serum

(Wongratanacheewin et al., 1988). Antibodies recognized mainly proteins of 45, 52, 56, 59, 65, 69, 75 and 81 kDa (Wongratanacheewin et al., 1991), which are associated to the surface tegument, reproductive organs, eggs and ESPs (Boonpucknavig et al., 1986; Wongratanacheewin and Sirisinha, 1987). The protein profiles and immunogenicity of *O. viverrini* and *Clonorchis sinensis* are similar except for a 16-kDa protein found in *O. viverrini* that seems to lack in *C. sinensis* (Sirisinha et al., 1990).

In humans, there is a significant positive correlation of the IgG antibody titer, the intensity of the infection and the severity of disease, whereas serum IgA levels correlate more closely with age than with intensity of infection (Elkins et al., 1991; Haswell-Elkins et al., 1991; Pinlaor et al., 2012). In infected individuals, the level of serum antibodies decreased slowly but remained elevated for several months after the praziquantel treatment (Ruangkunaporn et al., 1994).

The fact that prevalence and intensity of infection in humans do not decline with age in the absence of treatment, arguing against the existence of exposure-related resistance (Upatham et al., 1984; Haswell-Elkins et al., 1991), suggests that reinfection occurs, despite the strong cellular and humoral immune response elicited by the parasites as it has been observed in human infections (Wongratanacheewin et al., 1988) and immunized mice (Wongratanacheewin et al., 1991). However, experimental studies in *O. viverrini* infected hamsters have shown a limited protection of the animals, which was conferred by previous infection or immunization (Reviewed by Sripa et al., 2018a).

The involvement of T cells in pathogenesis is supported by the fact that T-cell-deprived *O. viverrini* infected hamsters show less severe damage of the bile duct tract (Flavell and Flavell, 1986). In these animals, the parasite stimulates the expression of the Th1-inducing cytokine, IL-12, in the early stage of infection (2 weeks post infection), whereas the expression of the Th2-inducing cytokine, IL-4, and the regulatory cytokines, TGF- β and IL-10, are significantly increased in chronic and/or heavy infections, in particular at mucosal level (Jittimanee et al., 2007). This may indicate their role in disease progression as they may inhibit T-cell proliferation, leading to prolonged worm survival (Maizels and Yazdanbakhsh, 2003), and thus blocking an effective immunity (Jittimanee et al., 2012; Kaewraemruaen et al., 2016).

Haswell-Elkins et al. reported increased level of urinary nitrates and salivary nitrites in *O. viverrini*-infected subjects in Northeast Thailand that decreased following treatment with praziquantel (Haswell-Elkins et al., 1994). They assumed that specific T cells synthesize nitric oxide (NO) that reacts with superoxide anion (O_2^-) to form peroxynitrite, a highly reactive species that causes nitrative and oxidative DNA damage to the cells. Further, a 10-fold greater potential for endogenous nitrosation among people living in endemic areas with positive antibody titers for *O. viverrini* as compared to uninfected controls has been demonstrated (Pinlaor et al., 2005). Nitrosamines play a very important role in inflammation-associated carcinogenesis, especially if they are generated in situ and their production is both chronic and located in close proximity to cells containing P450 enzymes which can metabolize the nitrosamine to DNA methylating agents (Sripa et al., 2012a,b). As other liver flukes, *O. felinus* elicits a humoral immune response already detectable from the third week after infection (Armignacco et al., 2008, 2013; Traverso et al., 2012). The main antigens recognized by human antibodies have been associated to the tegument, muscles, uterus, gonads, intestine and eggs of the liver fluke, as showed by immune electron microscopy. These findings have led to the conclusion that the surface structures of liver flukes stimulate a low B-cell immune response, whereas the structures linked to the ES system of the parasite and their products contain main antigens able to induce B-immune response in man (Kotelkin et al., 2001).

Diagnosis

In non-endemic areas, liver fluke infections are very difficult to diagnose due to the lack of pathognomonic signs and symptoms and the decreasing number of professionals able to identify opisthorchiid eggs in stool samples (Yossepowitch et al., 2004; Pozio et al., 2013). In endemic areas, the presence of signs revealing injury of the bile ducts by ultrasound or other imaging techniques is suggestive of infection (Sithithaworn et al., 2007). The clinical diagnosis of liver fluke infections should be confirmed by the detection of eggs in stools.

Parasitological diagnosis

Fecal examinations by the Kato-Katz (KK) and the formalin–ether concentration technique (FECT) have been frequently used for diagnosis of liver fluke infections. At a worm burden >20 , the rate of egg detection by both methods is comparable with the worm recovery (sensitivity 100%), as it was assessed in autopsied subjects grouped according to the number of worms recovered from their liver (Sithithaworn et al., 1991). However, FECT seems more sensitive than KK for the diagnosis of extremely low burden infections and for the follow-up after treatment (Sithithaworn et al., 2007). Multiple stool sampling or the combination of different diagnostic tests should be considered to enhance diagnostic accuracy (Bergquist et al., 2009; Johansen et al., 2010). Promising results have been obtained with the multivalent flotation method (FLOTAC), which allows considerably larger amounts of feces to be examined and showed a considerably higher sensitivity than the classical methods (Cringoli et al., 2010). It is necessary to consider that there are several species of foodborne trematodes which have similar egg morphology (as Opisthorchiidae, Heterophyidae and Lecithodendriidae families), consequently, recognition of the egg morphology is essential for a correct diagnosis (Chai and Lee, 2002).

Detection of parasite antigens in stools

ELISAs for antigen detection in stools and urine from infected persons have been developed using monoclonal antibodies (MAb) to different recombinant or native proteins from *O. viverrini* (Chaicumpa et al., 1992; Sirisinha et al., 1995; Worasith et al., 2015) and *C. sinensis* (Nie et al., 2014). A sandwich ELISA using recombinant *O. viverrini* cathepsin F chicken IgY in combination with rabbit IgG antibody to the somatic *O. viverrini* antigens for coproantigen detection was applied for the diagnosis, exhibiting sensitivity and specificity of 93.3% and 76.7%, respectively (Teimoori et al., 2015).

Detection of parasite DNA in stools

The detection of parasite DNA, whether by PCR and sequencing or by Real Time PCR is very useful to identify cryptic infections. There are species specific PCR tests to identify *O. viverrini* (Ando et al., 2001; Wongratanacheewin et al., 2002), *O. viverrini* and *C. sinensis* (Le et al., 2006; Sato et al., 2009; Kim et al., 2009; Huang et al., 2012), and *O. felineus* (Pauly et al., 2003; Müller et al., 2007) from the different parasite stages. The sensitivity can vary depending on the test, reaching 100% in moderate to severe infections (eggs per gram > 1000); whereas in light infections (eggs per gram < 200), the sensitivity drops to 68.2% (Wongratanacheewin et al., 2002). The presence of PCR inhibitors in human fecal specimens can strongly reduce PCR sensitivity.

Serological diagnosis

The time between infection and the detection of antibodies in serum ranges from 3 to 8 weeks for *O. felineus* infections (Armignacco et al., 2008, 2013; Traverso et al., 2012; Pozio et al., 2013), and it is reported from 2 to 4 weeks for *O. viverrini* infection in hamsters, therefore, the detection of specific antibodies, mainly IgG, has been considered as a complementary tool to establish a definitive diagnosis of the infection (Sripa and Kaewkes, 2000).

The serodiagnosis of liver flukes infections has been attempted by different immunodiagnostic assays, producing results of varying degrees of sensitivity (Pinlaor et al., 2012). However, the specificity is limited by the cross-reactive nature of the antigens (Wongratanacheewin et al., 1988; Haswell-Elkins et al., 1991; Sirisinha et al., 1995; Sakolvaree et al., 1997; Sawangsoda et al., 2012). Among infected people, serum titers have been found to be higher in CCA than in with cholangitis cases. The detection of IgG and IgG4 in serum yielded good sensitivities (99.2% and 93%, respectively) but poor specificity (23.1% and 29.6%, respectively); whereas the detection of IgG and IgG4 in urine had much lower sensitivity (43% and 45.9%, respectively) but better specificity (64.5% and 67.2%, respectively) (Tesana et al., 2007).

ELISA is widely used in Korea for *C. sinensis* infections (Choi et al., 2003; Lee et al., 2010), with 93.1% sensitivity when ESPs are used as antigens and 87.8% when crude extract is used (Choi et al., 2003). Several recombinant proteins from *C. sinensis* have been produced and identified (Shen et al., 2009) and shown to be sensitive and specific for serodiagnosis of clonorchiasis, but not enough to replace crude extract (Hong and Fang, 2012).

According to Meniavtseva et al. (1996), immunoenzymatic tests show the best performance among the serological tests for the diagnosis of opisthorchiasis. An ELISA based on ESPs has been validated for *O. felineus* infection in humans from low endemic areas (Gómez-Morales et al., 2013).

Human treatment

Currently, the drug of choice to treat people with clonorchiasis or opisthorchiasis is a pyrazinoisoquinoline named praziquantel (2-[cyclohexyl(oxo)methyl]-3,6,7,11b-tetrahydro-1H-pyrazino[2,1-a]isoquinolin-4-one). Praziquantel increases the permeability of the worm tegument, inducing a muscle contraction and a vacuolization of the tegumental syncytium of the flukes. This drug is rapidly absorbed and peak serum levels occur 1–3 h after administration; then, it is excreted with bile and urine within 24 h. According to WHO, the recommended dosage of praziquantel is 25 mg per kg of body weight, 3 times a day on 2 consecutive days or 40 mg per kg of body weight in a single administration with a repeat interval of 6 or 12 months (WHO, 2011). This treatment gives 100% and 80–85% cure rate for *O. viverrini* and *C. sinensis* infection, respectively (WHO, 1995).

The second drugs of choice are the benzimidazole-derivatives mebendazole and albendazole. However, these two drugs are effective only when given over a long period or at high doses (Armignacco et al., 2008). The treatment of *O. felineus* infections with albendazole (10 mg/kg body weight daily in two doses for 7 days) failed to eradicate all the flukes from one patient involved in an outbreak in Italy (Armignacco et al., 2013). Tribendimidine is another candidate for liver fluke infections treatment. It is an L-subtype nicotinic acetylcholine receptor antagonist (Hu et al., 2009; Xiao et al., 2013). Clinical studies of tribendimidine conducted in Lao PDR showed efficacy similar to that of praziquantel, since the egg reduction rates of tribendimidine and praziquantel are 99.3% and 98.4%, respectively (Soukhathammavong et al., 2011).

Prevention and control

Prevention and control measures should be proportionate to the epidemiological situation. In high endemic areas, morbidity can be prevented or controlled by treatment, health education, improved sanitary conditions, and implementation of food safety measures (WHO, 1995; Sithithaworn et al., 2007). Successful results were obtained only when a mass praziquantel treatment was combined to an extensive improvement of the health care system and to socioeconomic development (Jongsuksuntigul and Imsomboon, 2003). The limited level of natural protective immunity generated after infection makes the development of a vaccine for the prevention of these zoonoses challenging. Major recent advances in post-genomic technologies have aided new antigen discovery, but liver flukes have largely resisted successful vaccine development efforts. Successful vaccination of hamsters has, nevertheless, been reported using *O. viverrini* exosome-like EVs and recombinant tetraspanin proteins derived from the surface of EVs (revised by McManus, 2020).

To prevent clonorchiasis and opisthorchiasis, freshwater fish should be cooked until the core reaches 65 °C for at least 1 min (EFSA, 2010). According to Lloyd and Soulsby (1998), metacercariae may be killed by freezing at −10 °C for 5–70 days, depending on the size of the fish. Metacercariae of *O. felinus* can survive in smoked fish causing human infections (Yossepowitch et al., 2004). Marinating does not kill *O. felinus* metacercariae present in tench muscles (Armignacco et al., 2008, 2013; Traverso et al., 2012).

Closing remarks

Diseases caused by liver flukes remain important threats to public health due to the high morbidity they cause in many parts of the world, mainly in developing areas. National sampling surveys calculate prevalence rates in which counties and small villages are absent, thus hampering control activities. More emphasis should be placed on surveillance, so that control interventions can be tailored to specific settings. Currently, treatment is entirely dependent on a small number of effective drugs. Whereas vaccination is recognized as one of the most sustainable control options, development of protective and therapeutic vaccines against these pathogens has proven exceptionally difficult due to the complexity of the life cycles of flukes and their capacity to evade host immunity. The strategy for control of foodborne infection clearly requires collaboration among all sectors of public health. Consumer education is crucial and once it is recognized, the infected person should be monitored for the development of bile duct cancer.

Introduction

The protozoan parasite *Cryptosporidium* causes a disease of remarkable global socioeconomic significance. The parasite affects both humans and animals causing acute gastroenteritis, abdominal pain, and diarrhea (Dillingham et al., 2002). Though the exact location of parasite varies between species, it most frequently abodes the gastrointestinal (GI) tract (Noordeen et al., 2002). The infection mainly affects children, resulting in chronic diarrhea which leads to child development impediment (Khalil et al., 2018; Korpe et al., 2018). Although the condition only symptomizes as a self-limited diarrhea in healthy adults, it manifests as a prolonged and persistent diarrhea in high risk associated patients such as immunocompromised, including HIV/AIDS patients (Kurniawan et al., 2013; Janssen and Snowden, 2020).

Even though Edward Tyzzer in 1907 discovered the genus *Cryptosporidium* spp., by first detecting *Cryptosporidium muris* in the gastric glands of laboratory mice, only by early 1980s the organism was observed as a pathogen. The parasite was named *Cryptosporidium* because of the lack of presence of sporocysts in the oocysts, a characteristic present in other Coccidians (Tzipori and Widmer, 2008). Also, *Cryptosporidium* organisms infect only the brush border of the intestinal epithelium, as opposed to other Coccidian parasites which infect deeper tissue (Feng et al., 2018; Janssen and Snowden, 2020).

Cryptosporidium spp. are categorized under the phylum Apicomplexa which also includes other well-known genera such as *Plasmodium* and *Toxoplasma*. Currently more than 40 species of *Cryptosporidium* have been found and are categorized as most and less frequently detected ones. The ones belonging to first category are *Cryptosporidium hominis* and *Cryptosporidium parvum*, and ones in the latter are *Cryptosporidium meleagridis*, *Cryptosporidium felis*, *Cryptosporidium canis*, *Cryptosporidium ubiquitum*, *Cryptosporidium cuniculus*, *Cryptosporidium muris*, and *Cryptosporidium viatorum* (Feng et al., 2018; Innes et al., 2020). Though so many species have been identified, more than 90% of cryptosporidiosis cases in humans is caused by *C. parvum* and *C. hominis*, and a few cases of *C. meleagridis* infections have also been reported (Xiao and Ryan, 2004). However, in immunocompromised individuals, *C. canis*, *C. felis*, *C. meleagridis*, *C. suis*, *C. muris*, and *C. andersoni* species have been detected (Fayer, 2010; Pumipuntu and Piratae, 2018). Most of the zoonotic infections in humans from cattle show the presence of *C. parvum* (Ryan et al., 2014). Absence of host specificity of *Cryptosporidium* spp. is responsible for infection in multiple hosts, such as mammals, marsupials, birds, reptiles, and fish (Zahedi et al., 2015; Leitch and He, 2012; Gerace et al., 2019).

Fig. 1 The new holistic approach of the systems medicine places cryptosporidiosis within the framework of the one health medicine considering the protozoan *Cryptosporidium* as member of the gut microbiota ecosystem, namely parasitome.

Cryptosporidiosis is primarily transmitted through the fecal-oral route by means of a zoonotic or anthroponotic modality, via contaminated water or food (Putignani and Menichella, 2010). Waterborne cryptosporidiosis outbreaks are the outcome of contaminated municipal water and recreational water (swimming pool, lakes, ponds). This occurs as *Cryptosporidium* in the oocyst stage of its life cycle can withstand disinfection which includes chlorination, aiding the parasite to sustain for extended duration in the environment. Foodborne outbreaks are also observed but with less frequency (Ryan et al., 2018). Apart from water and food borne outbreaks, transmission of the parasite can happen through hospital personnel, daycare centers, contaminated soil and carrier insects such as cockroaches and houseflies (Alpert et al., 1986; Dillingham et al., 2002). Inhalation of oocysts has been described as another mode of transmission, especially in children and immunocompromised patients (Tzipori and Ward, 2002). Oocysts have been detected in sputum and bronchial aspirates (Clavel et al., 1996; Mor et al., 2010). Considering the modes of transmission and travel hygiene parameters, *Cryptosporidium* is also described as the cause of traveler's diarrhea (Vanathy et al., 2017).

Nitazoxanide is currently the only FDA, EMA and PMDA approved drug for the treatment of cryptosporidiosis in most immunocompetent people, it helps to resolve diarrhea from the third or fourth day of treatment. However, the drug does not portray promising results in young children and immunocompromised individuals (Rossignol et al., 2001; Amadi et al., 2002; Bones et al., 2019).

Nowadays, the holistic approach of system medicine in infectious diseases can assist also in discovering new clinical traits of cryptosporidiosis, considering the pathogen *Cryptosporidium* spp. not as *single pathogen* but as a *pathogen within the complexity of the gut microbiota ecology*. This novel approach may provide new insights on the role of host response and environment in the physiopathology of the disease, contributing to its understanding and clinical management. The cryptosporidiosis can therefore be reinterpreted in term of the *one health medicine* perspective rather than in term of classical *human medicine* (Fig. 1).

Epidemiology

In the early spring of 1993, a widespread outbreak of acute watery diarrhea was registered among the residents of Milwaukee (Mac Kenzie et al., 1994). Some residents had confirmed *Cryptosporidium* infection and a sample of those presented with acute watery diarrhea consistent with *Cryptosporidium* infection. Authors investigated the Milwaukee water-treatment plants to perform tests for enteric pathogens, including *Cryptosporidium* oocysts that were identified in water from ice made in the Southern Milwaukee plant in the same period. The rates of isolation of other enteric pathogens remained stable, but there was more than a 100-fold increase in the rate of isolation of *Cryptosporidium*, associated to clinical manifestations included watery diarrhea, abdominal cramps, fever, and vomiting. Remarkably, up to 403,000 people had watery diarrhea attributable to this massive outbreak caused by *Cryptosporidium* oocysts that passed through the filtration system of one of the city's water-treatment plants. This report actually opened the avenue to the molecular studies on cryptosporidiosis linked to water- and food-borne transmission.

Nowadays, during the last couple of years in the global scenario, the number of reported cases of cryptosporidiosis has increased to three cases per 100,000. However, clinical symptoms estimate the actual frequency of infection to be 100 times higher than the number of reported cases (Shrivastava et al., 2017). Among children from underdeveloped countries such as Brazil, Venezuela, Indonesia, Thailand, South Africa, Ghana, India, and Bangladesh, who suffer from diarrhea, cryptosporidiosis accounts for 3–13% of cases. Whereas in children from industrialized countries such as Britain, United States, Canada, Australia, and Denmark who experience diarrhea, the *Cryptosporidium*-related diarrhea falls between 1% and 4%. Children are more prone to the infection as their immune system is not well developed. Early age and malnutrition contribute to immune system impairment state, hence favoring cryptosporidiosis (Vohra et al., 2012). Indeed, incidence of the GI cryptosporidiosis is significantly lower in industrialized countries

compared to low income countries. This occurs because there still exists many people in the latter countries, who are not privileged to basic prerequisites such drinking water and sanitation facilities (Shoultz et al., 2016; Gerace et al., 2019).

Generally, cryptosporidiosis is associated with combined primary immunodeficiency disorders which are inherited or *de novo*. Only a few studies on the association are available to understand the dangers of the infection and they do not portray the risk and prognosis of the disease in the primary immunodeficient individuals (Wolska-Kusnierz et al., 2007; Jo et al., 2002; Gomez Morales et al., 1996; Hayward et al., 1997; Jacyna et al., 1990; Kocoshis et al., 1984; Levy et al., 1997). Prevalence of cryptosporidiosis in the case of HIV infected in Africa is 3.8–73.6% (Tumwine et al., 2005). Whereas in the South Asia India has a prevalence ranging from 4.7% to 56.5% and Nepal has 10.7%, in Southeast Asia, Thailand has a prevalence rate of 8.8–34.4%, Cambodia 45%, Malaysia of 3–23%, and Indonesia 52.5%. In the middle Eastern Asia, Iran has a prevalence of 0.9–26.7% while in the Eastern Asia Korea has 10.5% (Iqbal et al., 2012). The prevalence is reported from 8% to 39% in European countries, 3.5% to 11.9% in North America, and 4% to 22.8% in South America (Iqbal et al., 2012).

In 2016, reports in the EU/EEA by 21/32 countries showed 3.8 confirmed cases per 100,000 population (ECDC, 2016). A study conducted in UK reports that for every reported case there were approximately 8.2 undiagnosed cases in the community (Tam et al., 2012). The occurrence of *Cryptosporidium* infection was also found to be 76.66% in malignant and 15% in nonmalignant patients. Immunosuppressive therapy in malignant patients contribute to the increase in infection (Al-Warid et al., 2012). Organ transplant recipients are also at risk because *Cryptosporidium* was observed as one of the most common infections among them (Hunter and Nichols, 2002; Vanathy et al., 2017). Interestingly, in a recent meta-analysis on parasitic diseases affecting solid organ transplantation recipients, intestinal protozoan parasites were detected in the 38.6% of cases published in the period 1996–2016, with *Cryptosporidium* spp. the most reported (Fabiani et al., 2018).

Cryptosporidium are omnipresent, except in Antarctica and infection occurrence is found to be high during the warm and moist months (White, 2020; Painter et al., 2016). In the United States, the infection commonly occurs from July through September. In England, the incidence occurs in separate peaks, in the spring where the disease is associated with *C. parvum* and farm animals, and the fall where *C. hominis* plays a role with a mode of transmission via recreational water (Chalmers et al., 2011, 2019). Factors such as differences in access to health care, sample processing, diagnostic practice and variation in reporting requirements, gives rise to a marked variability to the prevalence of cryptosporidiosis, thus making interpretation of surveillance data within and between countries difficult (Cacciò and Chalmers, 2016; Innes et al., 2020).

The *Cryptosporidium* infective stage

The thick walled oocyst is the infective agent in *Cryptosporidium* spp. The resistance to extreme environmental conditions can be attributed to the complex double layer glycocalix-lipid-protein matrix of the oocyst wall (Templeton et al., 2004). The outer glycocalix comprises of heteropolymers, followed by a middle lipid layer and an inner protein layer. The lipid layer has been earlier described to contain phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine, sphingomyelin, and cardiolipin (Jenkins et al., 2010). The protein layer consists of multiple *Cryptosporidium* oocyst wall proteins (COWPs) with cysteine-rich domains, giving rise to extensive disulfide bonds that provide rigidity to the structure (Spano et al., 1997). To top it all, a double layer is formed during oocyst maturation, where the outer wall is constructed first, and then the inner wall (Templeton et al., 2004).

Life cycle

The life cycle of *Cryptosporidium* has several developmental phases, completed within the GI tract of a single host (monoxenous life cycle) (Current and Garcia, 1991). The phases begin with asexual multiplication, followed by sexual reproduction.

Upon ingestion of oocysts by a susceptible host, excystation occurs, after forming sutures on the oocyst wall thereby releasing four infective sporozoites, usually in the upper small intestine. Excystation is known to be triggered by various factors including temperature, pH, bile salts and pancreatic enzymes (Bouazid et al., 2013). The motile sporozoites glide over the host enterocytes, and the organelles (rhoptries and micronemes) help attach it to the plasma membrane via mucin-like glycoproteins and thrombospondin-related adhesive proteins (Wetzel et al., 2005; Wanyiri and Ward, 2006; Chatterjee et al., 2010). This facilitates internalization resulting in the recruitment of vacuoles within the cell, forming an intracellular but extra-cytoplasmic parasitophorous vacuole at the apical surface of the enterocyte (Huang et al., 2004). Triggered by certain host and parasite driven factors, the sporozoite within the vacuole de-differentiates, and then differentiates undergoing morphological changes, finally transforming into a replicative trophozoite (Smith et al., 2005; O'Hara and Chen, 2011; Edwinson et al., 2016). The parasite is supplied with energy and nutrients via a tubular “feeder organelle” that connects it to the host cytoplasm (Huang et al., 2004; Umemiya et al., 2005).

The trophozoites then undergo asexual multiplication, known as merogony, to generate a type I meront containing 6–8 type I merozoites. The type I merozoites are similar to sporozoites and escape the parasitophorous vacuole to infect nearby host cells and develop into trophozoites, thus continuing the asexual life cycle and propagating the infection.

Alternatively, some of the type I merozoites can develop into type II meronts, containing 4 type II merozoites. These type II merozoites invade cells and undergo gametogony, differentiating into either microgamonts or macrogamonts. The microgamont produces 16 non-flagellated microgametes by nuclear division, which bud-off from the microgamont and fertilize an adjacent

macrogamont, forming a diploid zygote. Recent studies show that the class II membrane fusion protein hapless2 (HAP2) is essential for gamete fusion (Tandel et al., 2019). The zygote further multiplies twice in an asexual manner, termed as sporogony, to produce an oocyst containing four sporozoites. The resulting oocyst can be of two types: thin-walled or thick-walled (Thompson et al., 2008). The thin-walled oocyst excysts and autoinfects the host, capable of causing persistent and chronic infection. Whereas, the thick-walled oocysts are released into the environment through feces, allowing it to infect other susceptible hosts.

Molecular pathogenesis

The parasite life cycle within the host can result in tissue damage and loss of function of the intestinal barrier. In vitro studies report disruption of tight cell junctions, increased permeability, mal-absorption, release of lactate dehydrogenase, and increased rates of cell death (Adams et al., 1994). Moreover, villus atrophy, crypt hyperplasia, infiltration of the lamina propria have also been described. *C. parvum* attaches to intestinal and biliary epithelial cells via specific molecules presenting on host-cell surface membranes including Gal/GalNAc-associated glycoproteins. Subsequent cellular entry of the parasite depends on host-cell membrane alterations to form a parasitophorous vacuole via activation of phosphatidylinositol 3-kinase (PI-3K)/Cdc42-associated actin remodeling. How *C. parvum* exploits these host-cell processes to facilitate its infection of target epithelia is unclear. Sphingolipid-enriched membrane microdomains (SEMs) were detected in aggregations of host-cell SEM components at infection sites during *C. parvum* infection of cultured human biliary epithelial cells (i.e., cholangiocytes), with a membrane-targeted translocation of the acid-sphingomyelinase (ASM). Pharmacological disruption of SEMs and knockdown of ASM via a specific small interfering RNA (siRNA) significantly decreased *C. parvum* attachment and cellular invasion. Importantly, knockdown of ASM and disruption of SEMs significantly blocked *C. parvum*-induced accumulation of Gal/GalNAc-associated glycoproteins at infection sites by ~90%. Disruption of SEMs and knockdown of ASM also significantly blocked *C. parvum*-induced activation of host-cell and subsequent accumulation of Cdc42 and actin (Nelson et al., 2006). These pioneer results suggested an important role of SEMs for *C. parvum* attachment to and entry of host cells, likely via clustering of membrane-binding molecules and facilitating of *C. parvum*-induced actin remodeling at infection sites through activation of the PI-3K/Cdc42 signaling pathway (Nelson et al., 2006). SEMs are involved in cellular entry of several pathogens, including viruses, bacteria and parasites, and associated toxins. A well-known example is the cholera toxin which enters cells via its binding to ganglioside GM1, a common component in SEMs (Lafont and van der Goot, 2005) and that has been hypothesized also for *C. parvum* (Guarino et al., 1994).

The parasitic proteins, such as phospholipases, proteases, and hemolysins can directly cause cell damage and are associated with virulence (Bouazid et al., 2013). The involvement of Hemolysin H4 in membrane lysis allows pathogenic invasion of host cells (Okhuysen and Chappell, 2002). Moreover, the parasite has evolved various molecular mechanisms to regulate the parasite-host interactions and evade the host immune response. Certain parasitic proteins such as cysteine proteases (for example, cryptopain-1) and patatin-like phospholipases have been identified as modulators of the host immune response (Bouazid et al., 2013; Wilson and Knoll, 2018). Also, several studies on *C. parvum* show that it can suppress apoptotic pathways in the host cell by various mechanisms, including BCL2 and survivin signaling, in order to complete its life cycle (Karczuk et al., 2020). Additionally, Galluzzi et al., states that *C. parvum* is able to induce the ER stress response or unfolded protein response through PERK2/NRF2 signaling to prolong host cell survival (Galluzzi et al., 2017). However, during the later stages of infection pro-apoptotic factors are activated inducing death of host cell and surrounding uninfected cells (Laurent and Lacroix-Lamandé, 2017). Another mechanism of host cell-biology modulation involves microRNAs (miRs) and long non-coding RNAs (lncRNAs). One example is to induce over-expression of miR21 in the infected cell, which in turn downregulates expression of the anti-microbial chemokine CCL20 (Guesdon et al., 2015). Interestingly, the parasite is also capable of delivering gene transcripts into the host cell nucleus to regulate gene expression (Wang et al., 2017). Emerging evidences further suggest that parasitic lncRNAs are transported into the host cell to suppress host genes involved in several pathways including cell migration and adherence (Li et al., 2020).

Cytokines play an important role in host immune response, but in the case of disease progression, they can contribute to pathogenesis. The cellular and tissue damage by the parasite result in increased permeability of the intestinal epithelium leading to infiltration of immune cells. Higher levels of pro-inflammatory cytokines, including interferon gamma (IFN- γ), tumor necrosis factor (TNF- α) and interleukin 8 (IL8) have been observed, contributing to the pathophysiology. These cytokines liberate soluble factors thereby increasing the secretion of water and chloride ions, and decreasing the sodium absorption, causing osmotic diarrhea. Moreover, Halliez and Buret point out that neutrophil influx into the mucosa results in elevation of prostaglandin (PGE2) and prostacyclin (PGI2), that can alter ion transportation and enterocyte secretion in an enteric nervous system (ENS)-dependent or independent manner (Halliez and Buret, 2015). Ultimately, all these factors combined contribute to impairment of intestinal function and architecture, leading to loss of absorptive surface area, malabsorption and fluid loss in patients.

Host immune response

Both innate and adaptive immune responses are essential in combating *Cryptosporidium* infection. The immune capacity of the host organisms plays a decisive role in the progression and severity of pathogenesis. In general, cells of the innate immune system initiate the first response and subsequently evoke the adaptive response via B and T cells to clear the infection.

Innate immune response to the parasite

The infected intestinal epithelial cells (IECs) express pattern-recognition receptors as well as major histocompatibility complex (MHC) required for activation of innate immune system by means of pro-inflammatory chemokines (via MyD88 and NF- κ B signaling cascade) and anti-microbial peptides (Leitch and He, 2012). Subsequently, dendritic cells, macrophages and natural killer (NK) cells are recruited to the site of infection and mediate significant immune responses.

Interferons (IFNs) produced by these cells have been identified as major factors that confer protection against the pathogen in the early phases of infection. Type I IFNs, namely IFN- α and - β , have been found to be elevated soon after *Cryptosporidium* infection suggesting a protective role (Barakat et al., 2009). IFN- β is responsible for activating the stress signaling pathway by activating macrophages to produce nitric oxide (Vanathy et al., 2017). Moving to type II IFNs, IFN- γ has been stipulated as one of the main links between the innate and adaptive immune response in apicomplexan infections (Ivanova et al., 2019). IFN- γ produced by NK cells and other innate lymphoid cells (ILCs) in response to Th1 inducing cytokines IL-12, IL-15, and IL-18 is critical in activating the adaptive immune response. However, the exact mechanisms and signaling pathways involved in *Cryptosporidium* infection are yet to be delineated (Ivanova et al., 2019). Recently, Ferguson et al. investigated the role of type III interferons IFN- λ in the epithelial defense against *C. parvum* (Ferguson et al., 2019). IFN- λ is well-known to protect mucosal sites against viral pathogens (Mahlakoiv et al., 2015). In cryptosporidiosis, IFN- λ 3 was found to be significantly upregulated during the peak of the infection, suggesting their involvement in epithelial defense mechanism (Ferguson et al., 2019).

Adaptive immune response to the parasite

The specific adaptive immune response is the dominant factor in ultimately resolving the infection. Pathogen clearance mainly happens in a cell-mediated response fashion. In response to cytokine cues and antigen presentation by innate cells, the naïve CD4⁺ T cells differentiate into effector cells to mount an adequate immune response.

IL-6 and TGF β produced by dendritic cells help in the differentiation into Th17 cells. Th17 cells secrete IL17 recruiting neutrophils to the site of infection. Oftentimes increased IL-17 production can lead to pathogenesis and tissue damage. Furthermore, differentiation into Th1 cells is stimulated by IL-12 (secreted by macrophages and DCs) and IFN- γ (secreted by NK cells). Th1 cells promote phagocytosis, neutrophil degranulation, differentiation of cytotoxic CD8⁺ cells and IgG2 production. In addition, Th1 cells also secrete IFN- γ creating a positive feedback loop and have inhibitory effect on Th2 differentiation, thereby creating an initial Th1 dominant environment during cryptosporidiosis (Leitch and He, 2012). On the other hand, IL4 inhibits Th1 differentiation but stimulates differentiation of naïve CD4⁺ into CD4⁺ Th2 cells which induce eosinophil activation, production of IgG1, and secretion of IL-5, IL-4, and IL-10. Experiments demonstrate that Th2 cells are essential in eliminating the parasite, thus suggesting a balance between Th1 and Th2 responses (Lemieux et al., 2017). Although CD8⁺ T cells have been speculated to help clear infection, studies on mice show that they are not the foremost actors in adaptive immune responses against infection by *Cryptosporidium* spp. (Chen et al., 1993). Studies further reveal that humoral response through systemic circulation of pathogen specific antibodies (IgM, IgA and IgG) are not essential in clearing the parasite (Lemieux et al., 2017). However, they might have a supportive role in conferring overall protection.

To sum up, it can be said that the cytokine milieu at the site of infection will direct the host immune response. The Th1 and Th17 ratios can tip the balance towards pathogen clearance or pathogenesis. Correspondingly, a decline in CD4 population due to disease conditions can be directly associated with disease progression. AIDS patients with CD4 count < 200 cells/mm³ have been observed to exhibit severe infection, although they express high IgG/IgA and mucosal IgA. Other vulnerable groups include malnourished children, patients with hyper-IgM syndrome and patients under immunosuppressive drugs.

Clinical symptoms of cryptosporidiosis

The main mechanisms put forward for the underlying cause of symptoms are (i) increased permeability of epithelial cells, parasite induced cell death and villous atrophy; (ii) breach in the lamina propria and influx of inflammatory cells; and (iii) malabsorption and malnutrition due to loss of intestinal architecture.

The intensity of the infection and subsequent symptoms differ in children, immunocompetent and immunocompromised individuals. The disease may appear asymptomatic or manifest as a fulminant one. There occur cases where the infections may not manifest any symptoms in both immunocompetent and immunocompromised individuals (Vanathy et al., 2017).

In healthy individuals

Symptoms which appear in healthy individuals are self-limiting and mostly 5–10 episodes of watery diarrhea per day with mucus flecks. Nausea, abdominal cramps, low-grade fever, and anorexia are the other symptoms and these generally resolve within 2 weeks. But when chronic cryptosporidiosis develops in infants, they fail to thrive. Stunted growth and respiratory tract involvement also results in the case of malnourished children (Current and Garcia 1991; Vanathy et al., 2017).

In immunocompromised individuals

Incompetent individuals turn immunocompromised due to a virus infection, organ transplantation, malignancy, primary immunodeficiency, and long-term steroids usage. Hence, immunosuppressive patients can be categorized into HIV individuals and non-HIV individuals. In HIV individuals, the presentation varies from asymptomatic to fulminant condition. The symptoms may persist for days and patients tend to pass 3–6 L of persistent watery stools per day. Such patients show a CD4 count <200 cells/mm³ and as much as 17 L of the watery stool has been reported. The symptoms are found to range from chronic diarrhea to intermittent diarrheal illness (Manabe et al., 1998). With time the symptoms worsen, dwindling the survival chances of the affected.

In addition, in such patients, extra-intestinal manifestations involving several organs such as biliary tract with the right upper quadrant nonradiating pain are observed. The typical symptoms involve primary acalculous cholecystitis and sometimes sclerosing cholangitis, pancreatitis with elevated amylase level, and abnormal radiographic findings. Moreover, respiratory tract disease with symptoms such as cough, shortness of breath, wheezing, croup, hoarseness, respiratory failure, and hypoxemia are also recorded. From the sputum, tracheal aspirates, bronchioalveolar lavage, and brush biopsy specimen of infected individuals, oocyst can be collected (Current and Garcia, 1991). Other clinical presentations such as gastric outlet obstruction and esophagus causing dysphagia are also reported in such cases (Vanathy et al., 2017).

Whereas in non-HIV individuals, symptoms that appear are profuse watery diarrhea, anorexia, and weight loss. Reports also show that the infection can spread to the respiratory tract in these patients (Current and Garcia, 1991; Vanathy et al., 2017).

Diagnostics

Since none of the symptoms of cryptosporidiosis have been identified as pathognomonic, differential diagnosis is often required to differentiate from viral, bacterial and other enteric parasites. Laboratory verification includes microscopic examination, immunological methods, histology and molecular techniques. The routinely examined sample is feces for detection of oocysts, but sometimes small bowel aspirates, biopsies or tissue samples may be available. (Khurana and Chaudhary, 2018; Bouzid et al., 2013). Ideally three samples are collected because the oocysts are shed intermittently and the sample should be processed as per the guidelines in a safety cabinet since *Cryptosporidium* spp. are classified as biosafety level II organism (Smith, 2007; Khurana and Chaudhary, 2018).

Microscopic examination

Currently, microscopic examination utilizes either wet mount preparation or the smear stains with modified acid-fast stain or fluorescent stains. Preferably, the stool sample is concentrated by centrifugation or formalin-ether sedimentation. Under light microscopy the oocysts appear as smooth, colorless, spherical or slightly ovoid bodies of 3–8 µm diameter (Smith, 2007). To increase specificity and sensitivity several stains have been standardized, including acid-fast modified Ziehl-Neelsen (mZN) stain, safranin-methylene blue and fluorogenic auramine-phenol stains (Khurana and Chaudhary, 2018). Rapid test using auramine-phenol followed by a confirmatory test by mZN or Giemsa stain is often considered the gold standard method as it offers the highest combination of sensitivity and specificity. The advantage auramine-phenol or ZN stain provides is that stained oocyst can be scraped off from the slide for subsequent DNA extraction for speciation (Amar et al., 2001). Apart from the different approaches, the results are very subjective as the specificity relies on the skill of the microscopist. Moreover, other factors including turnaround time, performance in batch mode, hands-on time, consumables cost per test or batch, and specialist equipment determine efficiency of microscopy platform (Chalmers et al., 2011; Bouzid et al., 2013).

Immunological detection

Both antigen and antibody detection assays have been developed with sensitivity and specificity varying from 93% to 100%. While antigen detection tests are useful for diagnosis of acute infection, antibody detection tests are useful in seroepidemiological surveys.

Several antigen detection assays are available that use labeled antibodies. Fluorescence-labeled C-mAbs, monoclonal antibodies against oocyst wall antigens, are commercially available to detect the epitopes present on the surface of the *C. parvum* oocysts. However, fluorescence intensity will differ across other species and genotypes of *Cryptosporidium* spp. Thus it is advised to confirm the negative samples by using conventional methods or polymerase chain reaction (PCR) methods (Smith, 2007; Khurana and Chaudhary, 2018).

Another method is the use of antibodies that are labeled with enzymes to detect antigens. These techniques may have low sensitivity but does exhibit high specificity (98–100%) and also can be used to process a large number of samples in a short time (Smith, 2007; Kaushik et al., 2008; Khurana et al., 2012). Commercial antibodies are available for enzyme immunoassay (EIA) and enzyme-linked immunosorbent assay (ELISA) or immunochromatographic (IC) protocols. Since IC format produces rapid results, it is a more preferred technique among others in laboratories. EIA and IC kits can be used to detect pathogens individually or multiplexed with other pathogens such as *Giardia* and/or *Entamoeba histolytica*. These tests are suggested to be performed on fresh, frozen, or formalin-preserved samples and can be done in a short time and obtain multiple results in one reaction device (Khurana and Chaudhary, 2018).

Unlike antigen detection for routine diagnostics, antibody detection methods are mostly recommended for seroepidemiological surveys since it can detect elevation in titer, or antibody isotype switching. Different assays exist for antibody detection in which native or recombinant *Cryptosporidium* antigens are utilized and the latter is reported to exhibit higher specificity. Recombinant Cp41 are used to determine human seropositivity (Kjos et al., 2005) whereas, Cp23 helps detect longitudinal infection trends (Ong et al., 2005) and age-specific seroprevalence (Cox et al., 2005). Although antigen/antibody detection is highly specific, commercially available assays have varying sensitivities and most of them fail to detect pathogen load below a certain threshold.

Histology

Histological diagnostics on biopsies can detect parasite in the brush border of intestinal mucosa. *Cryptosporidium* is found to be small, basophilic, spherical structures ranging from 3 to 5 µm and appearing in rows or clusters (Fig. 2). Also, techniques such as PCR and immunohistochemistry may be performed on paraffin-embedded tissue sections (Scallan et al., 2011; Morgan et al., 2000). However, this procedure present various disadvantages such as requirement of invasive procedures and careful processing of the sample thus making it an expensive, time consuming technique not recommended for routine diagnosis (Khurana and Chaudhary, 2018).

Molecular methods

Molecular methods offer better accuracy, high specificity and increased sensitivity ranging from 1 to 106 oocysts (Smith, 2007). They are also rapid and reliable for speciation and finding transmission routes. Nucleic acid detection methods such as PCR-restriction fragment length polymorphism (PCR-RFLP), multiplex allele-specific-PCR (MAS-PCR), and quantitative real-time PCR are available. Gene targets such as 18S rRNA, TRAP C1, COWP, Hsp 70, and DHFR genes help in species identification (Smith, 2007). Whereas, GP60 and microsatellite markers are useful for subtype identification. The highly sensitive 18S rRNA based PCR-RFLP is one of the most widely accepted molecular technique for cryptosporidium diagnosis. During outbreaks, MAS-PCR is considered a valuable tool to differentiate between *C. hominis* and *C. parvum* using dihydrofolate reductase gene sequence (Gile et al., 2002).

A commercial test developed and validated by Milwaukee Health Department Laboratory, 19-plex Gastrointestinal Pathogen Panel using Luminex xTAG analyte-specific reagents (ASRs) can be implemented for differential diagnosis of diarrhea-causing pathogens which includes 9 bacteria (*Campylobacter jejuni*, *Salmonella* spp., *Shigella* spp., enterotoxigenic *E. coli*, Shiga toxin-producing *E. coli*, *E. coli* O157:H7, *Vibrio cholerae*, *Yersinia enterocolitica*, and toxigenic *Campylobacter difficile*), three parasites (*Giardia lamblia*, *Cryptosporidium* spp., and *E. histolytica*), and four viruses (norovirus GI and GII, adenovirus 40/41, and rotavirus A) straight from fecal specimens (Zhang et al., 2015). Recently, telomeric Chos-1 gene was targeted by a unique real-time PCR assay to identify subtelomeric regions of *C. hominis* and *C. parvum* and exhibited improved genomic analysis (Bouazid et al., 2016). Some studies suggest Loop-mediated isothermal amplification (LAMP) to be a useful diagnosis of genes of *Cryptosporidium* spp. (Bakheit et al., 2008; Khurana and Chaudhary, 2018).

Presently, during the diagnosis of cryptosporidiosis various technical and practical difficulties are posed since skilled technicians are obligatory. In addition, there is an increasing requirement for cost-effective, point-of-care diagnostics, especially in low resource settings and low income countries.

Fig. 2 *Cryptosporidium parvum* oocysts surrounding the brush border of ileum mucosa. Magnification 100×, stained by Giemsa. We thank the Laboratory of Pathology of Bambino Gesù Children's Hospital and Research Institute Rome, Italy, Dott. ssa Paola Francalanci and Prof. ssa Rita Alaggio.

Therapeutic landscape

The current treatment and management regime is mainly supportive care which include (i) replacement of fluids and electrolytes, (ii) nutritional support, and (iii) restoration of immune function. The only approved anti-parasitic drug till date is Nitazoxanide. The new drug development pipelines for cryptosporidiosis have been slow owing to the lack of animal models and in vitro culturing difficulties. Another hurdle is the presence of parasitophorous vacuole membrane (PVM) and feeder organelle that acts as a protective barrier and blocks uptake of drugs from the host cell (Mukerjee et al., 2015). Of late, technical advances in genetic engineering, cell culture, 3D organoid modeling, transgenic mice models and biocomputation methods have led to a better understanding of the parasite at a molecular level, paving way for numerous studies on new therapeutic targets and drugs (Heo et al., 2018; Bhalchandra et al., 2018; Bones et al., 2019).

Currently available drugs

Nitazoxanide, a broad spectrum anti-parasitic drug, has been shown to be effective against *Cryptosporidium* in immunocompetent individuals. However, the efficacy is lower in malnourished children and negligible in AIDS patients (Sparks et al., 2015). In transplant patients on immunosuppressive drugs, nitazoxanide and fluoroquinolone combination therapy have been demonstrated as a better approach (Bhadauria et al., 2015). Another case study in France reports that withdrawal of immunosuppressant and prescription of nitazoxanide in multiple sclerosis patients can help resolve severe diarrhea and clear the pathogen completely (Martinot et al., 2020).

Passive immunity using hyperimmune sera is another therapeutic intervention that has seen partial success. Reports say that treatment with hyperimmune bovine colostrum (HBC) in AIDS patients have not yielded high success rates (Mead, 2014). Since AIDS patients are one of the most vulnerable to this parasite with life-threatening manifestations, most of the research and clinical trials have been focused on management in AIDS patients. Several drugs including paromomycin, azithromycin, spiramycin, rifamycin, and bovine anti-cryptosporidium immunoglobulin have been tested for therapeutic efficacy. Out of these, paromomycin has shown notable activity, though comparatively lesser than nitazoxanide. Recently, a publication by Debnath and Cheriya states that the FDA approved drug octreotide, can be used as a first-line therapy for diarrhea in AIDS patients infected by *Cryptosporidium* spp. (Debnath and Cheriya, 2020).

Molecular targets for drug development

Technical advances in genomics and proteomics have expanded the therapeutic possibilities in cryptosporidiosis. Parasitic enzymes are significantly different from human enzymes making them reliable drug targets. Some of the notable strategies that are under investigation are described below.

Inhibitors of host-cell invasion

Cryptosporidium calcium-dependent protein kinases (CpCDPK), namely CpCDPK1, is one of the most described targets to block microneme secretion and prevent host cell invasion. CpCDPK1 is known to express throughout the life cycle implying a role in cell invasion and growth (Castellanos-Gonzalez et al., 2016; Kuhlenschmidt et al., 2016; Huang et al., 2017). In vitro experiments show bumped kinase inhibitors (BKI), including Pyrazolopyrimidine (PP-BKIs) and 5-aminopyrazole-4-carboxamide (AC-BKIs) to be effective in arresting CpCDPK1 activity (Castellanos-Gonzalez et al., 2016; Huang et al., 2017). Clan CA cysteine proteases, such as cryptopain-1, expressed in sporozoites have also been identified to participate in host cell invasion (Siqueira-Neto et al., 2018). Oral dosage of small molecule inhibitors of cryptopain-1, such as K11777, was successful in reducing infection in animal models (Ndao et al., 2013).

Inhibiting growth and metabolism

Several metabolic pathways and growth related enzymes have been recognized as promising targets for pharmaceutical intervention. Targeting thymidylate synthase dihydrofolate reductase (TS-DHFR), an important enzyme in the folate synthesis pathway, has been portrayed as an effective strategy in *C. hominis* and *C. parvum* (Mukerjee et al., 2015). The enzyme Inosine 5'-monophosphate dehydrogenase (IMPDH) involved in guanine synthesis is another target under investigation (Omolabi et al., 2020). Furthermore, the lipid kinase phosphatidylinositol-4-OH kinase (PI(4)K) has been reported as a potential drug target. Manjunatha et al. report successful treatment of infected immunocompromised mice using pyrazolopyridine KDU731 as a PI(4)K inhibitor (Manjunatha et al., 2017). Recently, Zhang and team has published a study demonstrating that blocking CpCDPK3 (expressed in sporozoite and merozoite stages) inhibits growth in vitro (Zhang et al., 2020).

Access to the Malaria Box compounds has enabled screening of several drug candidates that could be repurposed for cryptosporidiosis. Some of these notable compounds are inhibitors of parasite phenylalanine-tRNA synthetase (PheRS) enzyme and macrogamont development. Targeting prenyl synthases (Artz et al., 2008), histone deacetylase (Guo et al., 2018) and HAP2 (Tandel et al., 2019) have also been described as potential anti-cryptosporidium mechanisms.

Drug-resistance

While drug-resistance is a very well phenomenon for *Giardia* spp. treatments (Yukiko and Lars, 2015) limited evidences are reported for anti-cryptosporidiosis drugs. Indeed, there is currently no fully effective treatment for cryptosporidiosis, which has stimulated interest in anticryptosporidial development over the last 10 years with numerous lead compounds. In a recent study (Hasan et al., 2021), the results of a dairy calf efficacy trial of the methionyl-tRNA (CpMetRS) synthetase inhibitor 2093 and the spontaneous emergence of drug resistance was reported. Dairy calves experimentally infected with *Cryptosporidium parvum* initially improved with 2093 treatment, but parasite shedding resumed in two of three calves on treatment day five. Parasites shed by each recrudescence calf had different amino acid altering CpMetRS mutations, coding either an aspartate 243 to glutamate (D243E) or a threonine 246 to isoleucine (T246I) mutation. This is the first report of naturally emerging *Cryptosporidium* drug resistance, highlighting the need to address the potential for anticryptosporidial resistance and establish strategies to limit its occurrence (Hasan et al., 2021).

Vaccine development

An ideal vaccine against *Cryptosporidium* should be able to confer protection against both *C. parvum* and *C. hominis*. Many different types of vaccines are being explored for cryptosporidiosis.

Live attenuated vaccines are the most tried and tested type of vaccine that is able to provide long lasting immune memory. However, in the case of *Cryptosporidium* spp., replication is host dependent, therefore, large scale culturing of oocysts is challenging. Consequently, peptides, DNA vaccines and vaccine vectors pose as more reliable options. In addition, “prime-pull” vaccine strategy developed by Shin and Iwasaki can be a suitable choice for eliciting tissue specific T-cell memory (Shin and Iwasaki, 2012).

Several surface proteins of sporozoites and merozoites have been selected for the development of vaccines. Some the potent surface antigens that have shown promising outcomes include gp40/15, Cp12, Cp15/60, Cp21, p23 and COWPs (Checkley et al., 2015; Lemieux et al., 2017). DNA vaccines encoding Cp12, Cp21 and Cp15, among others, have demonstrated increased Th1 response in animal models (Yu et al., 2010; Wang et al., 2010). Studies in cattle reveal that immunization of pregnant cattle with recombinant p23 subunit vaccine confers passive immunity to calves via antibodies in colostrum (Askari et al., 2016). Several bacterial vector vaccines, for example *C. parvum* antigen-expressing *Salmonella* spp., are under evaluation for cryptosporidiosis. Experiments for prime-pull vaccine approach utilize DNA or bacterial vector vaccine to prime mice models, followed by intraperitoneal delivery of recombinant protein to boost the immune response (Lemieux et al., 2017).

Overall, there has been remarkable advancements over the last decade with in vitro and in vivo experiments presenting promising results for the development of potent drugs and vaccines in the near future.

Concluding remarks

One of the primary objectives of *Cryptosporidium* research is to reduce morbidity and mortality due to infection, especially in children and immunocompromised patients. Despite great progress, cryptosporidiosis still remains as one of the main human and veterinary health concerns worldwide. Some of the major milestones in this area of research is undoubtedly the establishment of long term in vitro culturing techniques and development of relevant in vivo disease models. This has enabled scientists to probe deeper into the molecular basis of parasite biology and parasite-host interaction. These findings in turn allow for development of better diagnostics and precise pharmaceutical intervention strategies.

Although great advances have been made in discovering promising drug compounds, none have moved to clinical trials yet. In this scenario practice of basic hygiene to prevent disease transmission is essential. Governments must ensure better management of waste treatment, plant and water treatment in order to minimize contamination. Precautionary measures and availability of reliable diagnostic are necessities, especially in low-resource settings and areas with livestock and poor sanitization. A vaccine for humans and livestock is the need of the hour, and is critical to lessen the global disease burden.

However, the current approach of system medicine in handling infectious disease can assist also in the clinical management of cryptosporidiosis, considering the *single pathogen* in the ecosystem of the gut microbiota ecology, host response and environment, within the framework of the one-health strategy.

Introduction

Cyclospora and *Cystoisospora* are both unicellular parasites from the Chromalveolata supergroup within eukaryotes belonging to the Coccidiasina protist group, known as Apicomplexa (Levine et al., 1980; Cox, 1993; Adl et al., 2005). They cause gastrointestinal disease mainly in the tropical and subtropical climates, especially in Central and South America, India, Africa, and Asia, although cases have also been reported in Europe and North America (Lindsay et al., 1997; Almeria et al., 2019). Thus, the two parasites have a worldwide distribution in both developed and low income countries. As suggested by the names, these genera belong to the class Sporozoasida (Almeria et al., 2019). Ingestion of sporulated oocysts in fecal contaminated food or water or other transmission vehicle causes infection in susceptible subjects, typically a diarrhea, with abdominal cramping, and possible anorexia, nausea, fatigue and weight loss, among others (Shields and Olson, 2003; Ortega and Sanchez, 2010; Legua and Seas, 2013; Li et al., 2020a). This is due to the fact that in the gut lumen the sporocysts excyst and released sporozoites invade enterocytes of the duodenum and jejunum, where undergo multiplication (Figs. 1 and 2). They present two types of multiplication, asexual and sexual, the last one generating microgamonts and macrogamonts and after fertilization the formed zygotes differentiate as environmentally resistant unsporulated oocysts which are excreted in the feces. Hence, parasite transmission is via the feco-oral route. An external stage is required for the oocysts to mature and become infectious (sporulation), with *Cyclospora* requiring more time than *Cystoisospora* (7–14 against 1–3 days) (Lindsay et al., 1997; Almeria et al., 2019).

The species infecting humans are *Cyclospora cayetanensis* and *Cystoisospora belli* (formerly *Isospora belli*). They are along with *Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium* spp. and microsporidia, among parasites causing “traveler’s diarrhea” although *C. belli* is reported as one the least common intestinal coccidia that can infect humans (Vassalos and Vassalou, 2012; Rodriguez-Morales and Castaneda-Hernandez, 2014). To these, *Toxoplasma gondii*, *Blastocystis* sp. and *Balantoides coli* must be added, and other protist, such as *Acanthamoeba* spp. and *Naegleria* spp., can be transmitted with contaminated water (Marshall et al., 1997; Lv et al., 2013; Plutzer and Karanis, 2016; Pozio, 2020).

C. cayetanensis and *C. belli* sporocysts have different size with the first one being smaller (Figs. 3 and 4) (Ortega et al., 1994; Lindsay et al., 1997). *Cyclospora* and *Cystoisospora* belong to the order Eimeriorina, although are classified in different families, based on genetic and morphological differences. *Cyclospora* is within the family Eimeriidae along with *Eimeria* and *Isospora*, while *Cystoisospora* in the family Sarcocystidae along with *Toxoplasma*, *Neospora* and *Sarcocystis* (Samarasinghe et al., 2008).

Cyclosporiasis and cystoisosporiasis (formerly isosporiasis) are definitely foodborne and waterborne illnesses related to poor sanitation areas, affecting young children, the elderly, and immunocompromised people, albeit in most of the cases infections are self-limiting (Shields and Olson, 2003; Giangaspero et al., 2015; Li et al., 2020a). Cases of cyclosporiasis in North America and Europe were also associated to importation of contaminated fresh food (Almeria et al., 2019; Li et al., 2020b). Both infections are more severe in immunosuppressed persons, notably in HIV-infected patients, being considered as opportunistic (Masur, 2015; Laksemi et al., 2020; Dubey et al., 2020). *C. belli* and *C. cayetanensis*, together with *Cryptosporidium*, may also be found in the biliary system (Noor et al., 2019; Dubey et al., 2020). For both *C. belli* and *C. cayetanensis* first line treatment is based on

trimethoprim-sulfamethoxazole (TMP-SMX) (Cama and Mathison, 2015; Suh et al., 2017). Here we have introduced features common to the two parasites and peculiar traits. In the following sections after a brief historical picture, for each of the two genera we report sections on (i) biology and epidemiology, (ii) clinical symptoms and histopathology, (iii) diagnosis and (iv) treatment and prevention.

Cyclospora

Among the first *Cyclospora* species, there are *Cyclospora glomericola* found in 1881 in an invertebrate host and *Cyclospora caryolitica* at the beginning of last century in the mole (Lainson, 2005). Ortega and collaborators in the 1990s demonstrated that *C. cayetanensis* infects humans causing gastrointestinal disease (Ortega et al., 1993, 1994); this is the only species reported to infect humans, and humans are the only known host for this species (Eberhard et al., 2000; Ortega and Sanchez, 2010). Twenty-two *Cyclospora* species are identified at the beginning of 2020 infecting myriapodes, reptiles, insectivores, rodents and primates (Shields and Olson, 2003; Ortega and Sanchez, 2010; Giangaspero and Gasser, 2019; Li et al., 2020a). Recently identified *Cyclospora* species are from rhesus monkeys *Macaca mulatta* and North American mole *Scalopus aquaticus* (Li et al., 2015; McAllister et al., 2018). Classification traditionally was by morphological characterization of the oocysts in the feces and now mainly based on molecular methods (Shields and Olson, 2003; Lainson, 2005; Ortega and Robertson, 2017). For *C. cayetanensis* nuclear, mitochondrial and apicoplast genome sequencing were performed (Qvarnstrom et al., 2015; Cinar et al., 2015, 2016; Almeria et al., 2019). In epidemiological studies mitochondrial genome comparison by combined use of PCR and next-generation sequencing has recently been proposed for speciation and genotyping of the parasite (Cinar et al., 2020).

Cyclospora cayetanensis

Biology and epidemiology

The oocyst is spheroidal with a bilayered wall, which typically autofluoresces under UV light, as for other coccidia. *Cyclospora* and *Cryptosporidium* appear green when exposed to 450–490 nm light while under 365 nm UV *Cyclospora* looks blue (Fig. 4I) and *Cryptosporidium* violet (Ortega and Sanchez, 2010; Almeria et al., 2019). Sporocysts contain both Stieda and substieda bodies at a localized region of the wall, which are places where breakdown by the action of bile salts and trypsin begins (Cox, 1993; Ortega et al., 1994). Most recently, Dubey et al. showed all the developmental stages of the parasite in the gallbladder surgically removed

Fig. 5 Stages of *C. cayetanensis* in 0.5-µm sections of gallbladder. Toluidine blue stain. Schizont with three merozoites (A), a macrogamont (B), microgametes (C). Adapted from Dubey JP, Almeria S, Mowery J, and Fortes J (2020) Endogenous developmental cycle of the human coccidian *Cyclospora cayetanensis*. *Journal of Parasitology* 106: 295–307, with permission.

from an HIV-infected patient with cholecystitis (De Gorgolas et al., 2001; Dubey et al., 2020). After epithelial cells invasion by the excysted sporozoites, these within parasitophorous vacuoles (PV) round up and subsequently form schizonts, where multiple merozoites develop by schizogony (asexual multiplication in which the nucleus divides into four or more nuclei before merozoites are formed). Merozoites are pear-shaped or slender (banana-shaped) (Fig. 5A). Besides, sexual multiplication occurs when in some merozoite-invaded cell microgamonts (male) and macrogamonts (female) form (Ortega et al., 1997). Uninucleated macrogamonts contain several wall-forming bodies while microgamonts seat many flagellated microgametes (Fig. 5B and C) (Dubey et al., 2020).

Only sporulated oocyst is infective. Sporulation occurs into the environment within 7–14 days at temperatures above 22 °C and consists of differentiation into two sporocysts each containing two sporozoites (Figs. 1, 3 and 4G) (Ortega et al., 1993; Sathyanarayanan and Ortega, 2006; Almeria et al., 2019). Fungicides, insecticides and common disinfectants do not stop it while is inactivated by cooking at 70 °C (Sathyanarayanan and Ortega, 2004; Ortega and Sanchez., 2010; Almeria et al., 2019; Giangaspero and Gasser, 2019). Cyclosporiasis outbreaks in cruise, in Europe and mainly in North America were reported, and associated with the consumption of contaminated fresh produce such as berries and leafy greens, often imported from endemic regions (Almeria et al., 2019; Giangaspero and Gasser, 2019; Li et al., 2020a,b). Contamination has been found in pre-packaged vegetable products too, as well as in wastewater, chlorinated water and coastal waters not only in endemic countries. Nepal, Vietnam, Haiti, Guatemala, Perú, Ghana, Egypt, among others, are indicated as endemic for *C. cayetanensis*, nevertheless contaminated water has also been reported in Spain, Italy, Turkey and United States (Arizona) (Kitajima et al., 2014; Giangaspero et al., 2015; Almeria et al., 2019). Shellfish contamination has been reported in the Mediterranean Coast near Turkey and Tunisia (Ghozzi et al., 2017; Almeria et al., 2019). Parasite diffusion is certainly underestimated since many countries do not include *Cyclospora* in diagnostic protocols, furthermore climate change is expected to increase parasites spread, especially in the world poorest regions (Pozio, 2020). There is also a seasonality in cyclosporiasis, which depends in great part on the temperature (Shields and Olson, 2003; Kaminsky et al., 2016; Almeria et al., 2019). Some outbreaks and most of sporadic cases are due to travelling of persons, never exposed to the parasite before, to endemic countries, in which most of infections are self-limiting and followed by the acquisition of immunity to reinfection (Shields and Olson, 2003).

Clinical symptoms and histopathology

Prodromal stage is reported with flu-like symptoms although the onset is voluminous watery diarrhea, fatigue, and abdominal cramps. Other symptoms can be abdominal bloating, headache, constipation, loss of appetite, nausea, low-grade fever, chills and vomiting. Dehydration, malabsorption and weight loss can follow (Ortega et al., 1997; Lv et al., 2013). Duration can consist in few days as longer periods, even more than 1 month, mainly in people with deficits in their immune system (Li et al., 2020a). In cases of persisting symptoms which include dehydration, malaise, fatigue and sometimes fever, patients must be treated, otherwise extraintestinal complications can rise such as Guillain-Barré and Reiter syndromes, the last one involving more dysfunctions including oligoarthritis, urethritis and ocular inflammatory diseases (Richardson et al., 1998; Connor et al., 2001). Thus, chronic forms are not only in immunosuppressed and immunocompromised people, which anyway present the most severe form of cyclosporiasis, with complications such as a calculous cholecystitis (De Gorgolas et al., 2001; Ortega and Sanchez, 2010).

Jejunal biopsies show inflammation with altered mucosal architecture, edema, shortening of villi and hyperplasia of the crypts, disruption of the surface epithelium with extensive infiltration of lymphocytes (Ortega et al., 1997; Connor et al., 1999). HIV patients can show cholecystitis and removed gallbladder presented parasite infiltration in all parts (Fig. 5) (Ortega and Sanchez,

2010; Dubey et al., 2020). Presence of oocysts in patients suffering of tuberculosis has also been reported (Hussein et al., 2005). If not correctly treated, mainly in immunosuppressed patients especially those transplanted, severe dehydration due to cyclosporiasis as to other types of infectious enteritis may produce acute kidney injury, which can lead to chronic kidney disease (Lugo et al., 2021).

Diagnosis

Microscopic ova-and-parasite examination and molecular testing for DNA are used for diagnosis of *Cyclospora* infections (Almeria et al., 2019; Li et al., 2020a). Oocysts can be detected by microscopic analysis in multiple fecal specimens collected at 2–3 day intervals from a patient. *Cyclospora* oocysts are spherical and approximately 8–10 µm in diameter (Figs. 1, 3 and 4), which is the most important finding in the differential diagnosis of *Cryptosporidium*, whose oocysts are approximately half the size (4–6 µm, Fig. 4). Epifluorescence microscopy allows to exploit *Cyclospora* autofluorescence (as reported in the biology section, Fig. 4I) while conventional light microscopy is usually employed on stained smears. The modified Ziehl-Neelsen stain (acid fast) is recommended, where oocysts appear pink to red, although heated safranin staining is sensitive as well (Fig. 4B and E, respectively). Other staining methods are also used including Kinyoun, lacto-phenol cotton blue and Giemsa (Ortega and Sanchez, 2010; Giangaspero and Gasser, 2019). Concentrated samples by means for instance of sucrose or Percoll gradient centrifugation or formalin-ethyl acetate sedimentation (Ortega and Sanchez, 2010; Giangaspero and Gasser, 2019) enhance detection efficiency. Flow cytometry combined with autofluorescence was also efficiently used to detect *C. cayetanensis* on concentrated samples (Li et al., 2020a). In fresh stool specimens or more probably, in concentrates, *Cyclospora* oocysts can be observed by phase contrast or bright field microscopy; even better with differential interference contrast microscopy appearing as spherical bodies with a central or membrane-bound cluster of globules enclosed within a membrane (Fig. 4G) (Ortega and Sanchez, 2010; Cama and Mathison, 2015). Since these structures are similar to blue-green algal morula they were described in the first reports as alga-like and *Cyanobacterium*-like bodies, then associated to Coccidian-like bodies (Shlim et al., 1991; Ebrahimzadeh and Rogers, 1995).

Another method to identify *C. cayetanensis* is to allow sporulation in culture at 25 or 32 °C in 2.5% potassium dichromate, which occurs between the seventh and thirteenth day after excretion (Eberhard et al., 2000; Sathyanarayanan and Ortega, 2006; Almeria et al., 2019). Microscopic analysis reveals the difference in the structures of the oocysts, which only after sporulation present the two developed ovoid sporocysts with each the two sporozoites inside (Figs. 1, 3 and 4G). Excystation of sporozoites is possible after mechanical disruption of the sporocysts and exposure to trypsin (0.5%) and sodium taurocholate (1.5%) (Ortega et al., 1993). Parasite stages can be detected in microscopic examination of stained tissue biopsy sections, even kept fixed and paraffinated for very long periods (Fig. 5) (Dubey et al., 2020).

Molecular methods are the most sensitive; once even few oocysts are purified, quantitative PCR (qPCR) can be used for *C. cayetanensis* identification (Li et al., 2020a). Multiplex real-time PCR can detect with high sensitivity simultaneously *C. cayetanensis*, *Giardia lamblia*, *Cryptosporidium parvum* and other gastrointestinal pathogens (e.g. Biofire FilmArray Gastrointestinal Panel; Seegene Allplex™ Gastrointestinal Panel-Parasite Assay) (Buss et al., 2015; Ryan et al., 2017; Hannet et al., 2019; Yoo et al., 2019). *Cyclospora* DNA sequences amplified by PCR-based techniques are within the 18S small subunit ribosomal DNA (ssrDNA); the second internal transcribed spacer (ITS2) is a ribosomal DNA sequence more specific while another used locus is the 70 kDa heat shock protein gene (Shields and Olson, 2003; Lalonde and Gajadhar, 2008; Sulaiman et al., 2013; Giangaspero and Gasser, 2019). Commercial serological tests are not available although potential oocyst antigens have been identified (Hussein et al., 2020).

Treatment and prevention

Treatment is highly effective and consists of the systemic antiprotozoal drug trimethoprim-sulfamethoxazole (TMP-SMX, co-trimoxazole). In the presence of symptomatic infection TMP-SMX given orally (160 mg TMP and 800 mg SMX twice per day for 7–10 days or, in more severe cases as immunocompromised patients with relapse, four times per day for 10 days, and then twice per day for 3 weeks) (Shields and Olson, 2003; Giangaspero and Gasser, 2019). TMP-SMX is sold under the trade names Bactrim, Septra, Cotrim, Eusaprim and others. This treatment is important, mainly in immunodeficient individuals, and can also be used in patients with biliary disease (Verdier et al., 2000; Li et al., 2020a). In children, TMP-SMX at 5–25 mg/kg body weight (bwt) for 7 days is suggested, although a 3-day course has been shown sufficient in Peruvian children (Madico et al., 1997; Ortega and Sanchez, 2010). Alternative treatments in patients who have received transplantation or who are sulphonamide-intolerant or with sulfa allergy are the fluoroquinolone antibiotic ciprofloxacin at 500 mg twice daily for 7 days, and the thiazolide nitazoxanide at 9.5 mg/kg bwt for 3 days for failing with ciprofloxacin. These alternatives are not as effective as TMP-SMX, and may cause antibiotic resistance especially fluoroquinolones (Verdier et al., 2000; Li et al., 2020a). In patients with AIDS, it is also very important to treat the HIV infection as effectively as possible with antiretroviral drugs. Such treatment can strengthen the compromised immune system, and usually helps to control diarrhea and other symptoms.

Prevention is strictly linked to good hygiene conditions, which can exclude fecal-oral transmission of infective oocysts. Hence, endemic regions are mainly in underprivileged and low income countries, with problems in water and food sanitation. Risk factors are the lack of toilet facilities even in developed countries, the extreme population density as in megacities, difficulty in water supply, especially for drinking water, lack in treating human sewage and improper use of that, for instance in agriculture (Pozio, 2020). Thus, when travelling in endemic countries it is recommended drinking bottled or boiled water and not eating raw produce.

Some outbreaks in developed countries were related to consumption of imported contaminated fresh produce that were difficult to clean thoroughly (including berries, leafy greens, cilantro, basil) or to ready to eat-packaged vegetables. Hence, also globalization of the food supply has increased the risk of exposure to this type of parasites (Ortega and Sanchez, 2010). Oocysts are not affected by commonly used chlorine concentrations and most other chemical disinfectants while sodium dichloroisocyanurate solution reduces parasite number (El Zawawy et al., 2010). Also, membrane filtration, treatment with magnesium oxide nanoparticles, boiling and microwave heating are effective in cyclosporiasis control (Ortega and Sanchez, 2010). Gamma-irradiation, treatment with either ozone or hydrostatic pressure or chlorine dioxide showed to be effective with similar parasites (Almeria et al., 2019; Li et al., 2020a). Furthermore, when well assessed, UV light could be the most practical and safe control method (Giangaspero and Gasser, 2019).

Finding the source of *C. cayetanensis* infection in outbreaks in both non-endemic and endemic countries is essential to stop infection propagation. Beshearse et al. (2021) reported that in United States *C. cayetanensis* is estimated to have majority transmission through the foodborne pathway. Oocysts detection in vehicles such as raw vegetables and fruits is usually performed after specific washing protocol using a filter bag whose filtrate is then concentrated (Shields et al., 2012) although efficient concentration will be possible only when antibodies against *C. cayetanensis* can be available (Almeria et al., 2019). Several molecular methods have been investigated to identify different strains or geographic origin, such as sequencing the polymorphic region of mitochondrial genome and multilocus sequence typing (MLST) in nuclear DNA (Guo et al., 2016, 2019; Nascimento et al., 2019; Hofstetter et al., 2019). Mitochondrial DNA amplification is more efficient allowing to genotype almost all the samples, most probably due to the high copy numbers of the mitochondrial genome in *C. cayetanensis* (more than 500 copies estimated) (Tang et al., 2015). These procedures have allowed to distinguish at least two major groups; one including the American isolates (both North and South) and the other the Chinese specimens. Some similarity was found for China and Nepal specimens and for certain aspects for Nepalese and Indonesian ones (Guo et al., 2019). The worldwide diffusion of *C. cayetanensis* diagnostic tests, along with the monitoring of water sources, bathing and sewage waters, are recommended. Coastal waters may be easily monitored analyzing wild shellfish samples for parasite DNA since they retain and concentrate parasites while filtering large volumes of water (Ghozzi et al., 2017). Melt curves and gel electrophoresis of quantitative PCR products allow differentiating very rapidly the parasite isolates (Guo et al., 2019). In addition, it is mandatory to continuously check imported food and, above all, to spread health education worldwide, including the importance of proper hand washing.

Cystoisospora (previously Isospora)

The genus *Cystoisospora* includes species infecting mammals which were reclassified in 2005, previously belonging to the genus *Isospora* (Barta et al., 2005). Now the last genus is also called *Atoxoplasma*, and contains only species infecting birds (Schrenzel et al., 2005; Samarasinghe et al., 2008). In 1977, Frenkel proposed the new genus *Cystoisospora* for the two facultative two-host, feline species *Isospora felis* and *Isospora rivolta*, having monozoic tissue cysts (MZTC, containing a single asexual stage called zoite) in the rodent intermediate host (better considered paratenic since it is only a transport host where the parasite does not develop) (Frenkel, 1977; Lindsay et al., 1997). Analogous structures are formed by *C. belli* in human tissues (Fig. 6) (Lindsay et al., 1997). Then, genetic differences were found between species from non-mammalian and mammalian hosts (Samarasinghe et al., 2008). In addition, the oocysts from birds possess Stieda bodies, which conversely are absent in those from mammals (Barta et al., 2005).

Many studies have been performed on *Cystoisospora* species in cell cultures (Lindsay, 2019). After entering cultured cells some species, including *C. belli*, divide repeatedly by endodyogeny (asexual division with internal budding of two daughter cells from the common cytoplasmic mass of the parental cell), and *Cystoisospora suis* in in vitro models produces all development stages, comprehending the sexual ones (Lindsay et al., 1998). *C. suis* and *C. belli* cause serious disease in nursing pigs and in humans, respectively, while seldom *Cystoisospora* species do the same in nonhumans primates, dogs, or cats (Lindsay et al., 1997). *C. belli* was first described by Virchow in 1860, and identified as a human pathogen in 1915 among military personnel stationed in the Middle East during the World War I (Klassen-Fischer et al., 2011; Legua and Seas, 2013). Humans are the only known host for this species (Noor et al., 2019).

Fig. 6 Tissue cysts of *C. belli* in the spleen of an AIDS patient. A longitudinal view and a cross-section of tissue cysts are present. Note the tissue cyst wall (arrows) and the nucleus (open arrow) of one zoite. Magnification, $\times 1000$. Cystoisospora belli (previous *I. belli*)**Biology and epidemiology**

Oocysts are ellipsoidal with one end being blunt and the other tapered or both ends slightly tapered (spindle-shape) (Lindsay et al., 1997; Sherman, 2018) (Figs. 2, 3, 4 and 7). The oocyst has a bilayered wall, and has a large size as all the *Cystoisospora* stages, compared to *Cyclospora* and *Cryptosporidium* (Fig. 4). Mature sporulated oocyst measure on average $30 \times 12 \mu\text{m}$ (Minnaganti, 2018; Serrano-Batista et al., 2019; Dubey et al., 2019). When oocyst is excreted with feces it is unsporulated or partially sporulated (usually one sporoblast stage, Fig. 2). Then in appropriate conditions of temperature ($25\text{--}30^\circ\text{C}$) and humidity the sporoblast divides in two (Fig. 2), and after secretion of a cyst wall the two sporoblasts become sporocysts. These divide twice to produce four infective sporozoites each (sporogony, Figs. 2, 3, 4H, and 7) (Skinner, 1972; Lindsay et al., 1997). This oocyst maturation can range from 24 h to 10 days (Liu, 2010). At a low frequency *Caryospora*-like oocysts were also observed, characterized by oocysts containing one sporocyst with enclosed eight sporozoites (Jongwutiwes et al., 2007). The mature oocyst can remain infective in the environment for months (Sherman, 2018).

After ingestion of contaminated material, the sporocysts excyst in the small intestine and release sporozoites, which, after activation by bile and trypsin, become motile (McKenna and Charleston, 1982; Lindsay et al., 1997). Sporozoites invade epithelial cells lining the villi, and initiate schizogony (asexual multiplication) by repeated endodyogeny events (Fig. 2). Schizont and meront are terms for immature and mature asexual division stages, respectively, within PV in host cytoplasm. When the schizont and its host cell break, merozoites move into the gut lumen and penetrate uninfected enterocytes, where other replication rounds occur. After about 1 week some merozoites can shift to gametogony, the sexual phase with macrogamonts and microgamonts generating female and male gametocytes, respectively (Dubey et al., 2019). In patients with HIV asexual and sexual stages of *C. belli* have also been found in the epithelium of bile ducts and gallbladder, as for *C. cayetanensis* (Lindsay et al., 1997, 2014; Dubey and Almeria, 2019).

As other Sarcocystidae, *Cystoisospora* presents extraintestinal (EIN) tissue cyst stages, which are typically MZTC, that is a single centrally located zoite surrounded by a granular tissue cyst wall (Fig. 6) within a PV. That is, some sporozoites and/or merozoites leave the intestine and form dormant stages in EIN tissues. For *C. belli* they were mainly observed in AIDS patients, most frequently in *lamina propria* of the small and large intestine, lymph nodes, spleen, and liver (Dubey and Almeria, 2019). Recurrent cystoisosporiasis is believed to be due to reactivation of the zoites present in the MZTC and migration to the human intestinal tract (Lindsay et al., 2014). In an article published in 2019, Noor et al. in United States showed *C. belli* (inside intraepithelial PVs) in a great number of cholecystectomy specimens, and on a cohort of 22 more recent resections from patients with functional gallbladder disorder (biliary pain in the absence of gallstones or sludge) reported a prevalence of 27%. They suggested that *C. belli* is more prevalent among immunocompetent humans than previously recognized and may reside in a relatively latent state in the gallbladder (as a commensal organism), only giving rise to symptomatic infection in the setting of pronounced immunodeficiency and/or immunosuppression (Noor et al., 2019).

C. belli is mainly found in the Caribbean, Central and South America, Africa, the Middle East, India and Southeast Asia (Lindsay et al., 1997). As *C. cayetanensis*, in endemic countries it is more prevalent in children, and immunodeficiency, malnutrition and poor hygiene are risk factors for cystoisosporiasis, although in immunocompetent subjects it is usually a transient, self-limited illness (Sasaki et al., 2004; Rodriguez-Morales and Castaneda-Hernandez, 2014; Laksemi et al., 2020). It has been found in patients with colorectal cancers and it has been implicated in traveler's diarrhea (Vassalos and Vassalou, 2012; Mahmoudvand et al., 2019; Caner et al., 2020). Nevertheless, also in the rest of the world it is an opportunistic parasite of patients with HIV/AIDS, with lymphoma and leukemia, and recipients of renal and liver transplants, thus receiving immunosuppressive therapy, although the prevalence was higher in AIDS patients from endemic regions (Sorvillo et al., 1995; Guiguet et al., 2007; Stark et al., 2009; Akateh et al., 2018; Noor et al., 2019; Tsutsui et al., 2021). It has also been reported to cause severe diarrhea in a French patient affected by rheumatoid arthritis on corticosteroid and immunosuppressive therapy (Post et al., 2018), and in an Italian case of Good syndrome, characterized by the association of thymoma, hypogammaglobulinemia, low or absent B cells in the peripheral blood and defects in cell-mediated immunity, which differently from HIV has higher CD4 T-cell count (Esvan et al., 2018). *C. belli* has also been reported as the cause of outbreaks of diarrheal illness in daycare centers and psychiatric institutions in United States in past century (Rodriguez-Morales and Castaneda-Hernandez, 2014).

Fig. 7 Oocysts of *C. belli* in the stool smear. Magnification, $\times 1000$. Adapted from Tsutsui T, Kakizaki Y, and Miyashita Y (2021) *Cystoisospora belli* associated persistent diarrhea in an AIDS patient. *Journal of Infection and Chemotherapy* 27(2): 348–349. <https://doi.org/10.1016/j.jiac.2020.08.010>, with permission.

Clinical symptoms and histopathology

In immunocompetent patients cystoisosporiasis usually presents as mild forms in adults, characterized by acute, nonbloody diarrhea, crampy abdominal pain, vomiting, fever. Disease is more severe in infants. Diarrhea lasts 6–10 days, with infection self-resolving in 2–3 weeks, sometimes continuing for other 2–3 weeks (Cama and Mathison, 2015). Protracted diarrhea with malabsorption, steatorrhea, dehydration and weight loss may occur and sometimes the syndrome can be fatal (Lindsay et al., 1997; Sasaki et al., 2004). In some patients, peripheral eosinophilia is observed, which is a distinctive feature of this pathogen (Legua and Seas, 2013). Infection may be chronic with recurrences. Immunocompromised hosts present more severe and prolonged diarrhea and extra-intestinal manifestations involving *lamina propria* of the intestinal mucosa, gallbladder and biliary tract, mediastinal and mesenteric lymph nodes, liver, pancreas and spleen (Masur, 2015; Akateh et al., 2018; Noor et al., 2019). As for cyclosporiasis and other intestinal parasites, there may follow in some patients a rheumatic syndrome as a result of direct infiltration of musculoskeletal structures or an immune mediated mechanism (Hussein et al., 2019). Reactive arthritis has been described in a patient with AIDS and thrombotic thrombocytopenic purpura and hemolytic uremic syndrome both were described in association with this infection (Gonzalez-Dominguez et al., 1994; Auwaerter, 2016). Recurrent infection may require, after therapy, indefinite prophylaxis (Legua and Seas, 2013).

Villous atrophy and crypt hyperplasia can be present, also large numbers of eosinophils in *lamina propria* and other increased inflammatory cells, mainly in severe infections. Widespread mucosal changes such as a granular appearance of duodenum and proximal jejunum are even associated with severe symptoms, and the lymphatics may be dilated (Lindsay et al., 1997; Klassen-Fischer et al., 2011).

Diagnosis

Because of the large size, unsporulated oocysts of *C. belli* can be visible unstained by light microscopy on direct fecal smears (Fig. 7), although repeated stool examinations and concentration procedures are recommended (Lindsay et al., 1997). Modified Ziehl-Neelsen stain (acid-fast, Fig. 4C) or autofluorescence (Fig. 4H) can help the identification. Other staining procedures can also be useful (e.g. Fig. 4F) (Cama and Mathison, 2015). Extraintestinal cysts have been highlighted with Periodic Acid-Schiff (PAS) with predigestion with the polysaccharide digesting diastase (PASD) (Akateh et al., 2018) although Swanson reported that this last staining procedure needs confirmation by alternative methods or expert parasitologist consultation since can give false positives (Swanson et al., 2018). Charcot-Leyden crystals and high fat content are often observed in stool specimens (Minnaganti, 2018). Molecular methods are more sensitive; multiplex real-time PCR were used for the detection of DNA of opportunistic protozoa in HIV patients, targeting for *C. belli* the ITS2 sequence (Ten Hove et al., 2008), and for detection of *Cyclospora*, *Cystoisospora* and Microsporidia, targeting for *C. belli* ITS2 and 5.8 s rRNA (Taniuchi et al., 2011). In case of suspected cystoisosporiasis with stool examination negative, parasites can be sought in duodenal aspirates, string tests or intestinal biopsies after hematoxylin and eosin staining, typical vacuolated epithelium may also be a clue (Lindsay et al., 1997). The fact that *C. belli* can elicit blood eosinophilia, in contrast to most of intestinal protozoa, is an important clue for its diagnosis (Marques et al., 2019). Moreover, diagnosis of cystoisosporiasis should suggest investigation for HIV infection (Minnaganti, 2018). Also, HIV-infected persons with low CD4⁺ cell counts appear at greater risk of acquiring this parasitic infection (Certad et al., 2003).

Treatment and prevention

Apart hydration therapy in case of severe diarrhea, treatment highly effective is oral TMP-SMX, as for cyclosporiasis (Cama and Mathison, 2015; Vassalos and Vassalou, 2012; Suh et al., 2017). Immunosuppressed patients and those with AIDS may require long-term prophylaxis (Legua and Seas, 2013). As alternative, pyrimethamine with sulfadiazine (or sulfadoxine) or, for patients who cannot tolerate sulfonamides, ciprofloxacin, or pyrimethamine plus folinic acid. The veterinary agent diclazuril, doxycycline, roxithromycin, nitazoxanide, albendazole, bismuth subsalicylate, furazolidone, metronidazole, and quinacrine have also been reported to have some efficacy (Lindsay et al., 1997; Vassalos and Vassalou, 2012; Minnaganti, 2018). Recently a report of a kidney transplant patient underlined as diagnosis can be sometimes very difficult and delayed, resulting in poor prognosis. The authors suggested their screening protocol for transplant candidates, including *Mycobacterium tuberculosis*, *Strongyloides stercoralis*, Hepatitis B and C virus, HIV, Cytomegalovirus, Human Herpesvirus 6 and 8 and Epstein-Barr virus, might be extended to *C. belli* (Marques et al., 2019; Akateh et al., 2018).

For prevention, epidemiological studies, and surveillance on potential infection vehicles such as food and water sources are basic. Contamination of fruit and vegetables has been reported in Ethiopia and Ghana (Li et al., 2020b). Isolates from HIV-infected patients showed after DNA amplification distinct restriction fragment length polymorphism (PCR-RFLP) patterns in the 18S small subunit ribosomal DNA (SSU rDNA) (Resende et al., 2011), which could be useful not only to characterize different clinical presentations but also for epidemiological trace-back investigations on cystoisosporiasis. Both *Cystoisospora* and *Cyclospora* are considered neglected waterborne protozoa due to few information on its frequency in the global water sources (Plutzer and Karanis, 2016). In this setting, low cost and sensitive test for these parasites are needed, to allow wide monitoring, able to avoid outbreaks of diarrheal diseases, that in the endemic Countries are the second-leading cause of death in children younger than 5 years (Giangaspero and Gasser, 2019).

Conclusions

Cyclospora and *Cystoisospora* infections are considered emerging infective diseases for several reasons (Legua and Seas, 2013; Hadjilouka and Tsaltas, 2020). Global warming is bringing more of either drought or rainfall intensity, which both effect increase of these parasites in endemic countries. Drought causes oocysts concentration in water while rainfalls and floods increase their spread (Semenza et al., 2012; Pozio, 2020). In non-endemic countries cases increase, due to rise of both, travelling to endemic countries and importation of fresh foods from those regions. Among industrialized countries, in United States and Canada many *C. cayetanensis* outbreaks have been reported in the last 25 years (Almeria et al., 2019; Legua and Seas, 2013; Hadjilouka and Tsaltas, 2020). Several cases both in United States and Europe were domestically acquired, occurring mainly during spring and summer months (Almeria et al., 2019; Legua and Seas, 2013). Moreover, tropicalization of climate could favor establishment of these parasites in new regions (Semenza et al., 2012; Pozio, 2020). Hence, it really is important physicians know *C. cayetanensis* and *C. belli*, in all aspects we have discussed.

Introduction

Cystic echinococcosis (CE) and Alveolar echinococcosis (AE) are two zoonotic diseases caused by tapeworms belonging to the *Echinococcus* genus. CE is a cosmopolitan zoonosis present in countries across all continents excluding Antarctica, whereas AE is limited to the northern hemisphere (Deplazes et al., 2017). Human CE affects an estimated 1.2 million people worldwide, with 1–3 million disability-adjusted life years (DALYs) lost globally every year, although these figures are likely to be underestimated (Deplazes et al., 2017; Budke et al., 2006; Craig et al., 2007a). AE affects a lower number of individuals, but carries a significantly higher mortality burden, with a 90% mortality rate when untreated. Burden estimates for AE calculate the amount of lost DALYs to be around 660,000 (Torgerson et al., 2010). *E. granulosus sensu lato* (sl), the causal agent of CE, develops its cycle between dogs and other canids (definitive hosts) and livestock, especially sheep (intermediate hosts), with humans as an accidental intermediate hosts. In humans, the parasite develops to its metacestode stage, forming cysts in organs and tissues, mainly in the liver. CE is mostly endemic in rural areas where sheep (and other livestock) raising is practiced, such as central Asia and China, South America and Mediterranean countries (Deplazes et al., 2017). In 2012 a joint FAO/World Health Organization (WHO) expert group classified *E. granulosus* second among the top eight ranked food-borne parasites of global public health concern (FAO/WHO, 2012).

E. multilocularis develops its life cycle between small rodents (intermediate hosts) and foxes or dogs (definitive hosts). Its major areas of diffusion include the Tibetan plateau, northern China, central Asia and northern Europe. As such, AE is considerably less widespread than CE. However, even though both diseases have a significant impact on health systems, they are still scarcely studied in endemic areas and research is mainly carried out in referral centers (Brunetti et al., 2011).

This chapter highlights the main parasitological features of CE, while also covering the main diagnostic and therapeutic aspects of the disease.

The agents

Both CE and AE are zoonotic diseases caused by cestodes. The life cycle of both parasites, is shown in Fig. 1. The parasite is dependent on a predator-prey association involving mammalian hosts. This most frequently includes dogs and ungulates in the case of *E. granulosus* and small rodents and foxes or dogs in the case of *E. multilocularis*. However, it should be noted that both parasites are able to infect a range of hosts: in the case of CE, several ungulates species including pigs, horses, donkeys, buffaloes and cows can act as intermediate hosts, albeit with a reduced fertility rate of CE cysts. In the case of AE, a wide range of small rodents as well as raccoons can act as intermediate hosts, and reports of cats being infected have also been published. Other canids such as wolves can also act as definitive hosts (Romig et al., 2017a; CDC, n.d.).

The cycle starts when eggs are expelled with fecal material of infected dogs or other definitive hosts. These animals can be infected with a high load of worms and produce hundreds of eggs per day. Eggs are sensitive to exsiccation and to exposition to direct sunlight, but they can withstand high temperature provided that humidity is high enough, as well as low temperatures (Agudelo Higueta et al., 2016; Romig et al., 2017a).

Embrionated eggs are then ingested by intermediate hosts and hatch into oncospheres before penetrating the intestinal wall. From there, they are carried to the rest of the body via initial venous dissemination (Romig et al., 2017a; Tamarozzi et al., 2016a). Once they reach their target site, the oncospheres encyst, giving rise to the formation of the “classical” metacestode or hydatid cyst (Fig. 2). In fact, in all organs save for the bone, the cysts develop with the formation of three layers. The endocyst, which is the metabolically active part of the parasite, charged with producing brood capsules, protoscolexes and daughter vesicles. The parasite also produces a laminated layer (LL), an acellular membrane, composed by proteins, synthesized by the hexacanth larva as it develops and before synthesis for the germinal layer starts. This “protein wall” plays a major role in immune evasion. The adventitial part of the cyst (pericyst) is host-derived and is composed of fibrous connective tissue. Its presence is useful during surgical procedures as it provides a clear surgical reference for the operating team. While developing, the cyst becomes fluid filled and brood capsules containing protoscolexes (PSC) are released in the cyst fluid. PSCs are thought to develop within 10 months of infection, even though the exact timing has never been demonstrated and these data derive from animal studies (Tamarozzi et al., 2016a).

Fig. 1 Parasite life cycle. From Centers for Disease Control and Prevention (CDC). *Echinococcosis—Biology*. <https://www.cdc.gov/parasites/echinococcosis/biology.html>. Accessed September 9, 2019.

Fig. 2 Schematic representation of a CE cyst. From Brunetti E, Kern P and Vuitton DA (2010) Expert consensus for the diagnosis and treatment of cystic and alveolar echinococcosis in humans. *Acta Tropica* 114(1):1–16. doi:10.1016/j.actatropica.2009.11.001.

The cycle continues when a definitive host has access to the viscera of an infected intermediate host. Once ingested, PSC attach to the intestinal walls of the hosts and develop into adult worms. The cycle then starts again. PSCs cannot pass the intestinal walls of mammals. For this reason, the consumption of infected organs by intermediate hosts is not infective (Agudelo Higueta et al., 2016; Romig et al., 2017a; Tamarozzi et al., 2016a).

Humans are “accidental” or “dead-end” intermediate hosts, as they very rarely perpetuate the parasite life cycle. Humans get infected with the ingestion of eggs present on food or contaminated, unwashed hands. After infection, most of the times the cysts develop in the liver or lungs (50–70 and 10–20% of cases respectively), due to the initial hematogenous spreading via the portal veins and inferior vena cava. The spleen is the third anatomical location by frequency (10–15%) while other organs such as the bone, heart, brain are more rarely involved (Agudelo Higueta et al., 2016; Romig et al., 2017a; Eckert and Deplazes, 2004).

The structure of AE and CE cysts shares these baseline characteristics, however the way the lesions induced by the two parasites are is profoundly different: while in the case of CE parasitic growth leads to the formation of a single cyst compressing and displacing the surrounding tissues, AE develops with the formation of multiple lesions that slowly erode target organ tissues. The different development of the two lesions is thought to be an adaptive response to the different kinds of intermediate hosts colonized by the two parasites: while in the case of CE larger hosts are usually infected, allowing for the growth of a uniloculated lesion, AE prefers smaller intermediate hosts with reduced space for growth and a reduced life span: a more aggressive growth and faster lesion development would be needed to ensure parasite survival (Romig et al., 2017b). Another key difference is the localization of the cysts, which are in AE located in the liver in 98% of cases, with extra-hepatic localization very rarely described (Wen et al., 2019).

CE classical and molecular epidemiology

As previously stated, CE is particularly present in areas where animal husbandry is practiced and is a cosmopolitan zoonosis, present in all continents except Antarctica (Deplazes et al., 2017; Wen et al., 2019). The only territories that have been declared free from CE are small island nations or regions, namely Finland, Iceland and New Zealand (Fig. 3).

The epidemiology of CE has not been well investigated in several countries that are thought to be endemic on the basis of the presence of previously reported human cases and of animal surveys (Deplazes et al., 2017). However, a complete evaluation of the epidemiology of CE would require the collaboration of several parties, including public health authorities, medical and veterinary experts (Brunetti et al., 2011). This often proves impossible, hindering control efforts. For this reason, the exact epidemiology of CE in most of Africa is not clearly known, as well as in parts of Central Asia and South America (Deplazes et al., 2017; Angheben et al., 2017; Gestal et al., 2015). While efforts to clarify the animal epidemiology of CE rely on animal studies including surveys on

Fig. 3 Map showing the distribution of *E. alveolaris* (Panel A) and *E. granulosus* (Panel B) in the world. From Deplazes P, Rinaldi L, Alvarez Rojas CA, Torgerson PR, Harandi MF, Romig T, Antolova D, Schurer JM, Lahmar S, Cringoli G, Magambo J, Thompson RCA and Jenkins EJ (2017) Global distribution of alveolar and cystic echinococcosis. *Advances in Parasitology* 95: 315–493. doi:10.1016/bs.apar.2016.11.001.

slaughtered intermediate hosts and on dogs (Scala et al., 2017; Conchedda et al., 2016; Craig et al., 2007b; Lahmar et al., 2013; Boufana et al., 2015), a complete evaluation of CE animal epidemiology requires enormous commitment from public health authorities. In fact, in many countries where CE is hyperendemic, animals are often slaughtered at home and the offals are then left on the street for stray dogs to feed upon, or given to house dogs (El Berbri et al., 2015; Benchikh ElFegoun et al., 2016). In several countries this practice is partly due to religious reasons as the ritual killing of animals in the house is a practice diffused in prevalently Islamic countries (El Berbri et al., 2015). However, the lack of abattoirs designated for the slaughtering and inspections of animal carcasses may represent an aggravating factor (Lahmar et al., 2013; Ducrotoy et al., 2015; Torgerson et al., 2003). Studies have also shown that when abattoirs are present, inspections by veterinarians are often badly conducted due to the scarce commercial value of offals from sheep (El Berbri et al., 2015). Protocols for the appropriate disposals of offals from abattoirs are often lacking as well (Benchikh ElFegoun et al., 2016).

The epidemiology of human CE has been assessed in research projects and by public health authorities (Tamarozzi et al., 2017, 2018; Chebli et al., 2017; Macpherson et al., 2004). China, one of the most endemic countries worldwide, currently manages the widest public health surveillance network in the world. However, in many instances human surveillance programs are often lacking or non-existent. For instance, in Italy CE is not a notifiable disease (Brundu et al., 2014), and public health estimates have been conducted on the basis of Hospital Discharge Records, which are an imperfect tool as they leave out outpatients and asymptomatic cases (Tamarozzi et al., 2015). Recently, results from ultrasound (US)-based surveys carried in Bulgaria, Turkey and Romania show that a consistent proportion of patients with CE were not aware to carry the infection, which was expected. Active cysts were found in all ages and both sexes. The presence of active cysts in young patients may indicate continuing transmission. Most cysts were inactive, which is an expected result considering that they tend to spontaneously progress towards inactivation (Tamarozzi et al., 2018). However, the most relevant result of Tamarozzi and colleagues was showing that surveillance systems for CE are often lacking information. In fact, the survey carried out in Romania looked at around 1% of the country's rural population and found approximately the same number of cases notified by hospital records in the whole country in that same year (Tamarozzi et al., 2018). The study shows well that official notification systems often underestimate the number of cases, as in Romania the projections obtained by the researcher showed that around 151,000 people could be affected by the disease and be asymptomatic, and that 40% of the patients may carry active cysts (Tamarozzi et al., 2018). The result is even more impressive considering that estimates for the global burden of CE until now gave the number of patients infected at one to three million people (Budke et al., 2006).

Human studies include seroprevalence surveys (Fomda et al., 2015; Cetinkol et al., 2017; Akalin et al., 2014; Himsawi et al., 2019; Manciuilli et al., 2017). These studies aim to estimate the prevalence of CE based on the number of subjects with a positive serology for CE. However, the immunology of CE is complex and false positives in seroassays may be cross-reactions or reflect environmental exposure to parasitic antigens without the establishment of an infection (Tamarozzi et al., 2016a). Subjects with positive serology but negative imaging often revert to seronegative after a relatively short time, hence seropositivity should not be a marker for early infection (Hernández et al., 2005). However, although McPherson and colleagues demonstrated the superiority of US over serology in the assessment of CE epidemiology over 20 years ago, serosurveys continue to be employed (Macpherson and Milner, 2003; MacPherson et al., 1987).

Initial distinctions among different strains of *E. granulosus* were made on a morphological basis by spotting differences in adult worms in the definitive hosts or metacystodes and protoscoleces in intermediate hosts. Currently, *E. granulosus* is considered a species complex comprising nine genotypes (Romig et al., 2017a; Kinkar et al., 2016). Since the advent of molecular methods, morphological differences have been matched with genomic data and initially 10 genotypes were proposed (Moro et al., 2009). However, the G9 genotype has recently been assimilated to the G7 strain. The genotypes are grouped in different species and show a certain specificity for some species of intermediate hosts. The most prevalent genotype is G1, which accounts for 85% of CE cases worldwide and mainly parasites sheep in its cycle (Kinkar et al., 2016). Initial studies were conducted using molecular techniques ranging from RFLP-PCR to sequencing using two mitochondrial genes (nad1 and cox1) (Nikmanesh et al., 2014). The molecular resolution from these two genes has proven to be insufficient for in-depth analysis of phylogenetical relations between genotypes. For this reason, the use of nuclear genes has been explored in the last years (Kinkar et al., 2016, 2017). After new data were obtained from nuclear markers, the elimination of the G2 genotype has been proposed (Kinkar et al., 2017). However, a consensus still must be reached on this point. All known genotypes but G4 have conclusively been shown to be able to infect humans (Agudelo Higuaita et al., 2016).

AE classical and molecular epidemiology

AE has a significantly narrower distribution area compared to CE (Fig. 3) as its main endemicity area is located in some Asiatic regions, although it is also found in northern Europe with parts of France, Germany and other northern countries being affected. Human cases have also been reported in Hungary, and wolves infected by *E. multilocularis* have been found in northern Italy. In the Americas, while northern American regions including parts of the US and Canada are known endemic regions, recent surveys have confirmed an expansion of areas where the parasite is present, although this might just be due to increased sampling efforts and the impact of these findings on the epidemiology of human AE cases is still uncertain. Molecular markers for the characterization of AE include sequencing studies and the use of microsatellite markers. More specifically the EmsB marker, has proven useful in the execution of phylogenetic studies (Umhang et al., 2014, 2016, 2021).

Immune response in intermediate hosts

CE immune response in intermediate hosts

CE infection generates a complex immune response, as the parasite passes through several stages while in the body of the intermediate host. Briefly, studies on the immune response to infective oncospheres have shown that infection by oncospheres elicits a strong immune response, which is able to kill most parasites within days (Tamarozzi et al., 2016a). Oncospheres elicit a strong antibody response, acting together with complement to mediate protection against oncospheres, with the help of neutrophils. This strong immune response has been harnessed to develop the EG95 vaccine, that has proved highly efficacious in trials in several geographic regions (Tamarozzi et al., 2016a). The protection elicited by the vaccine can also be transmitted to the offspring of vaccinated animals via colostrum. The vaccine has been developed for the parasite G1 genotype and its efficacy against other genotypes is still unknown. This same initial immune response may be the basis of the high seroprevalence rates found in several studies, but no experimental data so far were produced to substantiate this hypothesis (Tamarozzi et al., 2016a; Fomda et al., 2015).

The immune response has been frequently investigated by using a mouse model where PSCs are injected in the peritoneum, mimicking secondary echinococcosis deriving from spillage of hydatid from ruptured cysts. The initial immune response has been shown to be of a Th1/Th2 phenotype, with an increased expression of interleukin (IL-) 4, IL-5, IL-10 and interferon (IFN-) γ (Petrone et al., 2015a,b; Wang et al., 2014). Studies have shown that the parasite is then able to downregulate both arms of this mixed immune response, which allows for parasite survival. Inflammation around the cysts (i.e., in host derived tissues) has been shown to be less prominent in live cysts than in degenerating cysts (Tamarozzi et al., 2016a). This may suggest that with the parasite proceeding towards inactivation, the mechanisms that allow for parasite tolerance are also less efficacious, allowing for a renewed immune response (Petrone et al., 2015a,b). However, the relationship of causality between cyst inactivation and inflammation in the host tissue still must be clarified, as cyst inactivation may well be the consequence of the renewed inflammation rather than its cause (Tamarozzi et al., 2016a). Parasite survival in the host does not rely solely on the isolation of the parasite from the host through the barrier effect of the LL. Actually, the LL has been shown to allow the exchange of molecules between the metacestode and the host (Tamarozzi et al., 2016a). This is proven by the high level of anti-hydatid cyst fluid (HCF) antibodies produced in intermediate hosts, and more recently by the detection of exosomes (vesicles that contain a variable parasite-derived and host-derived cargo and that may represent a future target for diagnostic or therapeutic approaches) in HCF and plasma of hosts (Cwiklinski et al., 2015; Siles-Lucas et al., 2017a; Fratini et al., 2020). Furthermore, host immunoglobulins are found in HCF (Tamarozzi et al., 2016a). While the LL does allow for the exchange of molecules between host and parasite, it also has immunomodulatory properties as shown by its ability to inhibit activation of antigen presenting cells and complement activation (Tamarozzi et al., 2016a; Gottstein et al., 2017).

HCF contains parasite molecules with immuno-active properties, involved in the complex immune-mediated interplay between the parasite and the host (Siles-Lucas et al., 2017b). Antibody, and more recently cytokine, in response to components of the HCF are explored and used for the immunodiagnosis of CE (Carmena et al., 2006).

AE immune response in intermediate hosts

Opposite to what is observed in CE, AE elicits a strong granulomatous response. Cellular immunity plays a major role in the immune response to AE infection and genetic background also has an influence in determining the efficacy of immune response (Vuitton et al., 1989). An initial Th1 response changes gradually to a mixed Th1/Th2 during the chronic phase of AE. Various cytokines (including IL-4, IL-5, IL-13, and IFN- γ) are produced. However, the most relevant are regulatory (IL-10 and transforming growth factor (TGF-) β), whose level has been shown to be increased in advanced disease stages (Zhang et al., 2012).

The Th2 to Th1 shift is observed in liver tissues in the early phases of infection (Wang et al., 2014). As in CE, enhancing Th1 immune responses, especially by acting on the innate immunity using IL-12, IFN- α , and TNF- α , increases resistance to *E. multilocularis* both in experimental mice and in humans (Liance et al., 2000).

Fibrosis formation, also induced by TGF- β seems to also have a role in host protection. However, fibrosis explains several clinical complication of AE. *In vitro* interactions have been shown between *E. multilocularis* vesicular fluid and some immune pathways involving PD-1/PD-L1, CTLA-4, LAG-3 and TIM-3 (Bellanger et al., 2017). The PD-1/PD-L1 pathway inhibits lymphocyte proliferation in the development of tumors and is over-expressed at the chronic stage of experimental AE (Jebbawi et al., 2021). Another promising checkpoint is the T-cell immunoreceptor with immunoglobulin and immunoreceptor tyrosine-based inhibitory motif domain (TIGIT) and its CD 155 ligand. TIGIT expression is increased and correlated with lesion activity in animal models and AE patients (Zhang et al., 2021). Studies have shown that TIGIT has a role in the exhaustion and functional impairment of natural killer (NK) cells in AE models (Zhang et al., 2021).

In *E. multilocularis* infection the LL has an important role in immune modulation. Immune-modulatory molecules are polysaccharide-containing antigens such as Em2 (G11), antigen C, EmP2, and Em492, a neutral glycosphingolipid, and novel mucin-type glycoforms. EmAP, a protein antigen, induces antibodies associated with disease severity and resistance to treatment in AE patients and causes the production of Th2-type cytokines (Vuitton and Gottstein, 2010).

Immunological applications in the diagnosis of CE

Diagnostic assays based on the detection of immune responses to parasitic antigens have shown considerable variability in results; this surely partially due to heterogeneity of antigenic preparations and lack of standardization in preparation of single antigens (Pagnozzi et al., 2016). Furthermore, the influence of different genotypes on the diagnostic efficacy has been scarcely explored. Native or purified versions of HCF and of the two main antigens of HCF, AgB and Ag5, have been investigated and used from the serodiagnosis of CE (Siles-Lucas et al., 2017b). Both molecules are expressed in all parasitic life stages have been shown to have immunomodulatory properties, but their biological role still has to be completely explored (Tamarozzi et al., 2016a). Other antigens such as EgTeg, EgTPx have been isolated but their role in *E. granulosus* immunity is not clear and they are not used in current serological assays (Tamarozzi et al., 2016a).

Recombinant antigens have been proposed to overcome the lack of antigen standardization. Some of these antigens (2B2t, rAgB/2) (Manzano-Román et al., 2015; Hernández-González et al., 2012, 2018; Li et al., 2003) have been tested in the diagnosis of CE (see below) with promising results (Manzano-Román et al., 2015; Hernández-González et al., 2012, 2018; Li et al., 2003). However, most studies assessing the diagnostic performance of new serological tests have been carried on small cohorts of patients and without including a crucial piece of information, cyst stage, which is one of the key variables influencing serology responses, together with cysts number, localization, size, and previous treatment (Li et al., 2003; Manterola et al., 2005, 2007; Baraquin et al., 2017). Seroassays have been shown to be falsely negative in a high proportion of both active (particularly CE1) and inactive cysts.

Besides antibodies, other host-derived molecules like interleukins, for example, are involved in the immune response to *E. granulosus* infection. As mentioned before, *E. granulosus* seems to be able to cause a switch in the immunophenotype from a Th1 or mixed Th1/Th2 phenotype to a down-modulated environment (Petrone et al., 2015b). This observation has been used to study changes in the expression of different IL levels during infection (Petrone et al., 2015a,b). In particular, IL-4 produced by whole blood stimulated with purified AgB has been proposed both as a diagnostic marker and as a marker of cyst activity (Petrone et al., 2015a, 2020, 2021).

Another recent advancement in the understanding of parasite biology, with potential diagnostic exploitation is represented by microRNAs (miRNAs), another class of molecules that have been intensively studied recently in both infectious and non-infectious diseases, as alterations in the composition of a host or parasite miRNome or in miRNA expression levels of these small molecules may give information on the status of such processes (Coakley et al., 2015; Tsitsiou and Lindsay, 2009). For instance, they have been studied in infections by *Schistosoma japonicum*, *Schistosoma mansoni* and *Fasciola hepatica* (Gantier, 2010; Lu and Rothenberg, 2013; Silakit et al., 2014; Arora et al., 2017). In the case of *E. granulosus*, miRNAs from infected sheep have been shown to be differentially expressed in strains that had MHC profiles resistant or susceptible to *E. granulosus* infection (Macchiaroli et al., 2015; Cucher et al., 2015). miRNA levels were also altered in humans with active cysts (Mariconti et al., 2019; Örsten et al., 2021). Further studies are needed to assess the potential of miRNAs for the diagnosis CE in general and specifically for active infections.

Immunological applications in the diagnosis of AE

In the case of AE, the role of cytokine assays has also been studied recently, with preliminary results showing a potential role for the use of IL-4 as a marker to differentiate AE and CE. Several cytokines have been shown to differ in expression between AE infected patients and healthy controls. However, further studies are needed to assess the applicability of cytokine assays in the diagnosis of AE (Petrone et al., 2020; Ma et al., 2020). Cell-free DNA has also been proposed as a marker for the diagnosis of AE as well as for the follow-up of treated patients (Baraquin et al., 2018; Fan et al., 2021), but its limited availability outside of referral centers is likely to impair its widespread use.

CE—Clinical presentation

Primary infection

In most cases, CE infection in humans is asymptomatic, and is diagnosed while the patient is undergoing imaging for other reasons (Agudelo Higuaita et al., 2016; Brunetti et al., 2010). Some patients have symptoms related to CE cysts, which vary depending on their location. While CE can theoretically affect all human organs, most patients carry a CE cyst in the abdomen, either in the liver (50–70%) or the spleen (5–15%) (Brunetti et al., 2010). In this instances symptoms are fairly non-specific and include abdominal pain, discomfort and the perception of a mass in the abdomen if the cyst is very large. Spleen CE has practically the same symptoms as liver CE, while other locations in the abdomen are less frequently observed.

If CE cysts are in the lungs, which are the second localization by frequency, patients can experience cough or thoracic pain in the case of uncomplicated cysts (Cappello et al., 2013).

Brain and cardiac CE cysts tend to be symptomatic since the limited space for the expansion of the cysts (Polat et al., 2003; Hamamci et al., 2004). This also applies to bone CE, where cysts grow with a branching pattern and do not develop the classical cyst structure (Papanikolaou, 2008; Neumayr et al., 2013).

Complicated cysts in the abdomen or lungs are usually symptomatic. A classic complication of lung CE is the elimination of cyst fragments via the airways after the formation of a cysto-bronchial fistula (Brunetti et al., 2010). Mechanical complications can also interest the biliary and urinary tract, as well as blood vessels. For instance, cysts near the Inferior Vena Cava (IVC) occasionally may leak into this blood vessel, with the release of parasitic material causing disease dissemination, potentially including pulmonary

embolism (Akbulut et al., 2013; Jaussi, 2009; Poyraz et al., 2016). Cyst rupture occurs (Neumayr et al., 2011) but no study has assessed risk factors for cyst rupture, though experts report cases of rupture of cysts located under the liver capsule, while in lung, large cysts can rupture after the initiation of ABZ administration (Brunetti et al., 2010).

Anaphylaxis is one of the most feared complications of CE, but is a rare phenomenon (Neumayr et al., 2011). In general, mechanical complications are also associated with IgE elevation and hypereosinophilia, due to the sudden release of parasitic antigens from the cyst (Agudelo Higuaita et al., 2016). Cysts can also become infected with the formation of an abscess.

Secondary infection

Secondary CE is defined as the appearance of cysts in anatomical sites that are distant from the primary localization, following spillage of cystic fluid and seeding of protoscoleces from the primary cyst. Due to the long natural history of CE and the fact that infections are diagnosed years after the initial contact with the parasite, it can be hard to establish whether patients have two primary localizations or if there has been disease spreading (Neumayr et al., 2013). This is particularly evident in the case of patients with bone localizations. Most of the cases of secondary CE are, however, due to the diffusion of scoleces in the abdomen following the rupture of cysts. Other localizations include cerebral, spleen, musculoskeletal CE following hematogenous spreading and lung CE due to embolization (Neumayr et al., 2013; Prati et al., 2016). Patients with peritoneal CE are often asymptomatic. Musculoskeletal CE tends to be more symptomatic, because of mass effect with compression of vascular or nervous structures (Agudelo Higuaita et al., 2016; Cattaneo et al., 2019).

CE diagnosis and follow-up

Imaging

It is the main tool for CE diagnosis. In particular US has a key role in the diagnosis of CE as a portable, non-invasive imaging method. A US-based diagnosis of CE requires the detection of pathognomonic signs of CE cysts. The first attempts at a US classification were made by Gharbi. Later, Caremani and colleagues also proposed their own classification (Macpherson et al., 2003). At the start of the 2000s, the WHO-IWGE produced a standardized classification (Brunetti et al. 2010). This classification essentially made some modifications to that proposed by Gharbi. The classification distinguishes six cyst stages and three groups of cysts (Fig. 4). CE1, CE2 and CE3b cysts are considered active, CE3a are considered transitional and CE4 and CE5 are considered inactive. These distinctions have led the WHO-IWGE to endorse a stage-specific approach to the treatment of uncomplicated CE cysts, which will be reviewed in more detail below.

Fig. 4 Stage-specific clinical management of hepatic uncomplicated CE cysts, in line with Expert Consensus recommendation (Brunetti et al., 2010). From Firpo G, Vola A, Lissandrin R, Tamarozzi F and Brunetti E (2017) Preliminary evaluation of percutaneous treatment of echinococcal cysts without injection of Scolicidal agent. *The American Journal of Tropical Medicine and Hygiene* 97(6):1818–1826. doi:10.4269/ajtmh.17-0468.

The classification and the stage-specific approach proposed by the WHO-IWGE are still far from being universally accepted although the situation has recently improved (Mirabile et al., 2019). Experience from the CE control program in the Rio Negro province of Argentina has shown that, given enough time and tutorship, general physicians with no prior education on US or CE can learn to use the classification and the stage-specific approach endorsed by the WHO-IWGE (Larrieu et al., 2011). Such programs are not widespread, however, as they require political and economic commitment from authorities, something which is rarely available for CE.

US allows for the diagnosis of CE cysts in the muscles and in lung CE if the cyst is adjacent to the pleura, as well as cardiac CE (Polat et al., 2003; Richter et al., 2003). Other anatomical locations that are not accessible to US can be explored by either CT scan or MRI, and X-ray in the case of lung CE, although this should be followed by a second level exam if surgery is deemed necessary (Stojkovic et al., 2012). CE cysts explored via contrast-enhanced radiological examinations do not show contrastographic impregnation. This can be detected around the cyst if pericystic inflammation is present (Polat et al., 2003). Stojkovic and colleagues showed that MRI is superior to CT for the diagnosis and staging of hepatic CE (Stojkovic et al., 2012). Currently, experts from the WHO-IWGE also recommend the use of MRI for extra-hepatic localizations (Tamarozzi F, personal communication). This is more complex for lung as lung MRI is often not available, even in industrialized countries.

US and other imaging methods also allow for the non-invasive follow-up of CE patients. While many cysts tend to evolve towards inactivity in their natural history, in diagnosed humans with active cysts they should do so in response to treatment (Tamarozzi et al., 2016a). In fact, sometimes the administration of treatment can help clarify the nature of a suspect CE lesion, as the administration of ABZ for as little as 1 month can cause the detachment of the endocyst in CL lesions of parasitic nature. A course of ABZ has also been shown to cause temporary cyst solidification, in CE2 and CE3b cysts (Rinaldi et al., 2014a).

Serology

Serological assays are widely used for the diagnosis of CE. Several techniques (ELISA, Western Blot—WB, IHA, EIA and Rapid Diagnostic Tests—RDT) have been developed for the diagnosis of CE. The first antigen used for the development of tests was native Hydatid Cystic Fluid (HCF), followed by native and recombinant antigens (Carmena et al., 2006; Manzano-Román et al., 2015). Problems regarding these different preparations have been illustrated in the Immunology section of this chapter. To date no study has rigorously assessed the role of serology in the differential diagnosis of CE. The current consensus on the use of serology is that it is complementary to imaging in the diagnosis of CE. Moreover, some studies have attempted to establish if these tests could be used in the follow-up of patients with CE, especially in surgically treated patients (Boubaker et al., 2014; Stojkovic et al., 2017). Surgical treatment of a CE cyst should entail the elimination of all antigenic stimuli on the immune system, and patients should ideally revert to seronegativity if no relapse or new infection occurs. This hypothesis is hard to study and verify, as several surgical techniques are used in the surgical management of CE, and there is no absolute guarantee that all the parasitic tissue is eliminated during surgery (Wen et al., 2019). Tests with native, purified and recombinant tests have been used and they have all shown that surgical patients cannot be followed-up by serology to detect relapses with the currently available tests (Stojkovic et al., 2017).

RDTs have also been developed for the diagnosis of CE and tested in a few studies. Most of these assessed the performance of serological assays in a hospital setting, some did not include information on cyst stage (Baraquín et al., 2017; Tamarozzi et al., 2016b; Gao et al., 2018). A recent study on the use of RDTs in resource-limited settings as shown a potential role as confirmatory tests in the presence of suggestive imaging (Manciulli et al., 2021). The detection of antibodies belonging to the IgG4 subclass has been proposed to be more specific than other serological methods, as well as to correlate with the degree of activity of CE cysts (Tamarozzi et al., 2016a). However, the study that came to this conclusion used HCF from equine cysts with a possible bias due to differences in the infecting genotypes. Moreover, the study did not report the stages of the involved cysts (Lawn et al., 2004).

For practical purposes, serology should never be used alone in the diagnosis of CE, as the presence of a lesion with suggestive characteristics is needed to justify the execution of serological tests. Furthermore, single center experiences, testing of multiple commercial assays and a systematic review of the literature have shown that the execution of a single test suffers from the fact that results of CE serology are influenced by several factors, both test-dependent (antigen choice, antigen batch variability, preparation method, test technique) and laboratory-dependent. Parasite-dependent factor (cyst number, stage and size) also play a role (Tamarozzi et al., 2016b, 2021a,b; Vola et al., 2019; Hernández-González et al., 2008). Ideally, two first line tests are initially employed, of which one is ideally WB (Tamarozzi et al., 2021a; Vola et al., 2019). As discussed above, no reliable serological marker for disease activity exists, as antibodies can persist for years after treatment (Hernández-González et al., 2008, 2018; Piccoli et al., 2014).

Cross reactions with other parasitic infections are also possible in CE, with *Theridion solium* and *E. multilocularis* cross-reactions being quite frequently present (Manzano-Román et al., 2015; Hernández-González et al., 2008).

Molecular and immunological methods

Molecular methods are not widely used in the diagnosis of CE in humans. PCR protocols have been developed for the diagnosis of CE in animals, using cyst samples from slaughtered animals (Piccoli et al., 2013), but parasitic DNA cannot be found in human serum, unless a cyst ruptures. In this case, DNA has also been found in the urine of patients. However, this is a rare instance and has little clinical utility in most patients (Chaya and Parija, 2014). The potential role of cytokine-based assays and exosome detection has been discussed above.

CE treatment

Surgery has been traditionally considered the first line treatment for CE. Several techniques have been proposed, either radical or conservative. From the end of the 1980s, a new class of drugs became available and showed activity against both CE and AE infections. Benzimidazoles are a class comprising several compounds, two of which are approved for human use and used in the treatment of CE: Mebendazole (MBZ) and ABZ. It soon became clear that medical treatment alone could not treat all CE cysts. The need for other treatments led to the development of percutaneous procedures, the most widely used being the Puncture, Aspiration, Injection, Respiration (PAIR) procedure. This technique was developed roughly at the same time by a group of researchers in Pavia (Filice and Brunetti, 1997) and in Tunisia (Gargouri et al., 1990). A second percutaneous procedure with percutaneous catheters was also developed for cysts larger than 10 cm (Brunetti et al., 2010). Over time, it also became clear that inactive cysts very rarely reactivate. As such, a Watch and Wait (WW) approach was also proposed for uncomplicated inactive cysts. All these approaches were taken into account when formulating the Expert consensus for the diagnosis and treatment of CE and AE, whose recommendations are summarized in Fig. 4 (Brunetti et al., 2010).

Medical treatment

MBZ and ABZ exert their anti-parasitic activity by blocking the formation of β -tubulin polymers within the staminal cells of the parasite. They have also been shown to interfere with glucose uptake from the parasite, which proves damaging to *E. granulosus* due to the key role of glucose in this parasite metabolism (Hemphill et al., 2014; Siles-Lucas et al., 2018). However, these drugs only have a parasitostatic activity in the treatment of CE, and it is thought that their effect is to impede the biological activity of the parasite while the immune system also fights the infection (Siles-Lucas et al., 2018). ABZ and MBZ are commonly used to treat other parasitic infections such as soil transmitted helminthiasis or neurocysticercosis (Horton, 2002). However, the duration of treatment for these infections is considerably shorter than the one required by CE and AE (Horton, 2002). Currently, drugs are administered over the course of months, as experts believe that this is required to exert an effect on cysts (Brunetti et al., 2010). ABZ and MBZ were initially administered in courses of 28 days with 1 week of suspension, due to concern on the presence of side effects such as hepatotoxicity and bone marrow toxicity. This was based on animal studies, but subsequent studies have shown the safety profile of both drugs with an acceptable risk/benefit ratio for patients undergoing prolonged administration (Horton, 1997, 2002). However, most national pharmacovigilance authorities have not updated the recommendations for the use of ABZ and MBZ in the treatment of CE. Currently, France is the only country to accept the administration of ABZ in a continuous fashion (Manciulli et al., 2018a). ABZ has now become the drug of choice in the treatment of CE, with MBZ playing a secondary role. This is largely due to the better bioavailability of ABZ which can be translated in a lower dose needed to attain clinical efficacy (Siles-Lucas et al., 2018).

Another problem with ABZ and less frequently MBZ is that the drugs can sometimes become unavailable, or are not available at all in some countries. In Italy ABZ shortages that have impacted on the treatment of patients (Manciulli et al., 2018a).

Other candidate molecules for medical treatment

Several compounds have been tested in vitro or in vivo to determine their possible anti-echinococcal activity. These include other benzimidazoles such as oxfendazole, flubendazole, fenbendazole, antimalarials such as mefloquine and artemisinin derivatives, anti-cancer drugs and antibiotics or antivirals (Siles-Lucas et al., 2018). Most trials outside the benzimidazole class in vivo have been carried out to assess combination therapies with benzimidazoles, not single therapy protocols (Siles-Lucas et al., 2018). Another interesting point is the search for new formulations of existing benzimidazoles to increase the drug penetration into the cyst, something which affects ABZ efficacy. Liposomal formulations have been tested, as well as tablets containing nanopolymers (Siles-Lucas et al., 2018). Sodium salts of ricobendazole have also recently been used and have been tested in a mouse model. Several compounds derived from medicinal plants have also been tested in both experimental and animal models, with none reaching human clinical experimentation thus far. However, the largest obstacle to assessing new medical treatments is their long duration (Siles-Lucas et al., 2018).

Surgical treatment

Radical and conservative techniques can be distinguished. In the former, CE cysts are completely removed from the liver parenchyma, with or without hepatic resection (Wen et al., 2019; Rinaldi et al., 2014b). Different techniques can also be distinguished based on an open or closed cyst approach. One of the most diffused is the “total cystectomy” or pericystectomy approach, which uses the natural cleavage plane formed by the pericyst to remove the entire cyst without opening it. In conservative approaches, only the parasitic material is removed, while the resulting residual cavity is managed by capitonnage, omentoplasty or other techniques (Rinaldi et al., 2014b). Recently, a standardized endocystectomy approach has been described by the group at the Heidelberg University Hospital (Al-saeedi et al., 2019). All open techniques should be executed by experienced teams and extreme caution should be used to avoid protoscoleces spillage from the cyst, as this is the most relevant risk factor for recurrence (Al-saeedi et al., 2019). The use of surgical sponges soaked with 20% hypertonic saline has been recommended since the establishment of the WHO-IWGE expert consensus (Brunetti et al., 2010). Since this solution is toxic for the peritoneum and

the biliary tract and can cause hyperosmolar coma, the surgical field should also be covered by sponges soaked in 0.9% NaCl solution (Al-saeedi et al., 2019). Currently, studies on surgical patients suffer from the same limitations of those focusing on medical therapy, as it is impossible to effectively generate evidence on the best treatment of uncomplicated cysts without randomized controlled trials (Rinaldi et al., 2014b). The same applies to the management of surgical complications, as one recent review found that questions are many and answers are lacking.

Cysts complicated by fistulization or rupture are generally treated by surgery, general conditions of the patient allowing. Infected cysts may be treated by surgery if percutaneous procedures are not available (Brunetti et al., 2010; Rinaldi et al., 2014b).

Percutaneous procedures

Percutaneous procedures were developed for the treatment of predominantly liquid CE cysts (CE1 and CE3a). The first technique to be developed was PAIR, and some other techniques have been proposed over time, all variations of the PAIR protocol, which sees a first step in the US-guided percutaneous puncture of the cyst, followed by aspiration of the cyst content, usually presenting as a clear, transparent fluid in young untreated cysts, while it becomes yellow and turbid in cysts that are spontaneously evolving towards inactivation or have been treated by ABZ (Rinaldi et al., 2014b; Brunetti et al., 2018; Örmeci, 2014). After aspiration, a scolicidal agent (hypertonic saline or alcohol) is injected in the cavity, and is left there for 20 min to attain cyst sterilization. After this, the fluid is re-aspirated and the patient is kept in observation for 24 h. The whole procedure is performed in the presence of an intensive care specialist, ready to intervene in the case of collateral effects, mainly anaphylactic reactions. It should be noted that these are possible but quite rare (Neumayr et al., 2011; Rinaldi et al., 2014b).

Variations of the PAIR technique have been proposed, and recently a procedure without the use of scolicidal agents has been proposed by our group (Firpo et al., 2017).

PAIR is recommended to treat cysts that are large more than 5 cm, while another kind of procedure using large bore catheters has gained ground as an alternative to surgical treatment in patients with large cysts (more than 10 cms) (Brunetti et al., 2010; Akhan et al., 2016). In this procedure, a catheter is inserted under US guidance in the cyst cavity, and is left in place draining the cyst content over days, while the patient is hospitalized. Scolicidal agents can be used in a similar fashion to what is done for the PAIR procedure (Brunetti et al., 2010).

Cysts that are larger than 10 cms can also be treated with PAIR, however this requires the use of a large bore catheter to progressively drain cyst content until a drainage of less than 75 ml is obtained on a daily basis (Brunetti et al., 2010).

More recently, a procedure relying on cyst aspiration has been applied in CE2 and CE3b cysts in the liver with excellent results due to the absence of relapses (Akhan et al., 2017), but its general applicability would require validation through the execution of a clinical trial.

Due to the use of scolicidal agents, patients undergoing percutaneous procedures should always be evaluated for the presence of a biliary fistula, especially if the cyst is larger than 7,5 cm. This has been shown to be a clear risk factor for the presence of fistulas (Rinaldi et al., 2014b). The fact that this evaluation ideally requires access to or to colangio-MRI has limited the use of percutaneous procedures in resource-limited settings.

All patients treated by a percutaneous procedure must undergo ABZ administration before the procedure and for the subsequent month, according to the WHO-IWGE (Brunetti et al., 2010). This recommendation is also valid for patients undergoing surgery and is based on data from animal models showing that in case of peritoneal dissemination of cyst content, 1 month of ABZ could prevent secondary CE. However, this recommendation is followed inconsistently in endemic countries (Manciulli et al., 2018b).

The last recorded clinical trial to date has regarded the use of ABZ post-operatively in percutaneously treated patients, conducted by colleagues from the University of Ankara. The group concluded that 1 month of ABZ is enough to reduce recurrence rates (Akhan et al., 2017).

Watch and wait

Although not strictly a “treatment”, watch and wait (WW) is recognized as a clinical management option for inactive cysts. Its rationale derives from the demonstration of the scarce reactivation rate of cysts that are found to be spontaneously inactive, or that have been treated according to the WHO-IWGE recommendations (Piccoli et al., 2014; Solomon et al., 2017; Stojkovic et al., 2016; Lissandrini et al., 2018). A limitation of currently published studies is that these are based on patients seen at referral centers for CE and the number of patients is not high enough to generate conclusive evidence. Generating data from hyperendemic countries is also hard, as in these settings surgeons tend to dominate the treatment of CE (Manciulli et al., 2018b). However, WW has been shown to avoid unnecessary treatment for patients, reducing risks and saving precious resources for health systems, as surgery for CE is costly (Narra et al., 2016).

Hints for a watch and wait approach have been suggested by a work considering CE3b cysts. In this paper, the authors concluded that CE3b cysts had an indolent behavior after receiving medical treatment, with the development of a low number of complications. The authors then suggested that a WW approach for CE3b cyst can be implemented in selected cases in which surgery is not strictly indicated and that are compliant with medical therapy and a subsequent long-term follow-up.

AE clinical presentation

As in the case of CE, the clinical presentation of AE can be subtle due to the slow natural history of the disease, with lesions growing during the course of years. Due to its radiological features, AE is often misdiagnosed initially, since symptoms are unspecific and radiological appearance can be quite similar to that of a malignant tumor. Jaundice is the most frequent symptom at presentation in acutely ill cases. However, the vast majority of cases are paucisymptomatic or asymptomatic at first diagnosis. Immunocompromised patients can present without symptoms more frequently, but also tend to show a faster progression towards end organ damage (Wen et al., 2019). Complications of AE include cholangitis due to biliary infection, abscess formation, and metastatic spreading either by contiguity or hematogenous dissemination (Vuitton et al., 2016; Brunet et al., 2015; Meinel et al., 2018). AE lesion progression has been associated with the presence of HLA-DR3 DQ2 haplotype as patients showed a more severe disease and a more pronounced Th2-type immune response, associated with a deeper tolerance status. Moreover, AIDS has been associated with an accelerated course of the disease, and the initiation of antiretroviral therapy usually corrects the immune defects and slows disease progression (Ran et al., 2016). Transplant patients are another category at higher risk for a faster disease progression, due to immunosuppressive drugs (Wen et al., 2019).

AE diagnosis

Imaging

As in CE, the main tool for the diagnosis of AE is imaging. Given that AE lesions tend to develop in a different fashion than CE cysts, the WHO-IWGE has introduced a staging system based on the TNM classification used for tumors. Classifications based on US, MRI and CT appearance have been proposed and are currently being used in clinical practice at referral centers (Kratzer, 2015; Kodama et al., 2003; Graeter et al., 2020a). The CT classification divides cysts into five subtypes based on morphological characteristics and it has recently been evaluated in the context of an international collaboration involving AE referral centers in China and Europe (Graeter et al., 2020b). In a recent paper, an update of the Kodama classification based on the use of MRI has been proposed, introducing two subgroups for lesions considered to be type III (IIIa and IIIb, based on the absence or presence of microcysts). Interestingly, the authors have advanced an hypothesis that would allow to establish a radiological progression of lesions through the different stages of the Kodama classification, as it was noted that type I and II lesions were more frequently present in Europe, where disease is diagnosed early, while type IV and V lesions were more frequently present in China, where in endemic area patients seek care late in the course of the disease. The authors of the proposed modification compared the introduction of these two subtypes to the introduction of the CE3a/3b categories used for CE. Further studies using PET-CT scans and MRI spectroscopy will be needed to establish the relationship between biologic viability of the various cyst subtypes and imaging features (Brumpton et al., 2021).

Based on overall imaging evaluation, AE can be staged with a staging system that follows the same structure as NTM staging used for tumors:

- PX Primary tumor cannot be assessed
- P0 No detectable tumor in the liver
- P1 Peripheral lesions without proximal vascular and/or biliary involvement
- P2 Central lesions with proximal vascular and/or biliary involvement of one lobe
- P3 Central lesions with hilar vascular or biliary involvement of both lobes and/or with involvement of two hepatic veins
- P4 Any liver lesion with extension along the vessels and the biliary tree
- N Extrahepatic involvement of neighboring organs [diaphragm, lung, pleura, pericardium, heart, gastric and duodenal wall, adrenal glands, peritoneum, retroperitoneum, parietal wall (muscles, skin, bone), pancreas, regional lymph nodes, liver ligaments, kidney]
- NX Not evaluable
- N1 Regional involvement of contiguous organs or tissues
- M The absence or presence of distant metastasis [lung, distant lymph nodes, spleen, CNS, orbital, bone, skin, muscle, kidney, distant peritoneum, and retroperitoneum]
- MX Not completely evaluated M 0 No metastasis
- M1 Metastasis

Scoring system: Stage I, P1 N0 M0; stage II, P2 N0 M0; stage IIIa, P3 N0 M0; stage IIIb, P1–3 N1 M0 or P4 N0 M0; stage IV, P4 N1 M0 or any P, any N, and/or M1.

Serology

Serological assays for AE suffer from the same limitations as the ones for CE. However, serological markers are more reliable for follow-up in the case of AE, since antibodies directed against the Em18 antigen have been shown to have good performances and can also be used to monitor response to therapy, given that imaging changes might occur over a longer time interval (Wen et al., 2019). A commercial ELISA using the recombinant Em18 antigen is available (*E. multilocularis* recEm-18, Bordier, Crissier, Switzerland).

AE treatment

AE treatment is challenging given the invasiveness of the disease, and it requires a multidisciplinary approach (Brunetti et al., 2010). The above-mentioned PNM staging system helps clinicians caring for AE patients choose an appropriate treatment strategy. Surgery is considered an option only in cases where radical resection of AE lesions is feasible, a situation which occurs only in one third of patients (Wen et al., 2019). Partial resection is currently not recommended due to poor results, while perendoscopic procedures carried out to manage complications such as biliary endoprosthesis or multiple stent insertions are accepted means. These procedures are currently an alternative to percutaneous procedures previously used together with medical therapy. Transplantation and *ex-vivo* liver resection followed by autotransplantation (ELRA) have also been used. However, the latter is scarcely used in Europe despite studies showing its efficacy on Chinese patients. Transplantation has been employed in AE patients, with good survival rates even in the presence of residual parasitic tissue in grafted livers. However, it is not frequently used in Europe due to the demographic characteristics of patients, who tend to present at a later age than Asian patients.

Medical treatment constitutes the other pillar of AE management. Prompt initiation of benzimidazole therapy is required in all cases, with the possibility to use continuous treatment, often required for the entire lifetime of the patient.

In patients with small and calcified lesions, with no FDG uptake on PET/CT, a “watch-and-wait” attitude can be followed. It is also applied when ABZ or MBZ withdrawal has been decided on the basis of serological and PET/CT negative results and in patients with radical resection after 2 years of ABZ or MBZ.

Echinococcosis control and surveillance

The control of echinococcosis has been hard to implement due to the very heterogeneous epidemiology of both AE and CE. For CE, efforts until now were mainly based on the use of dog deworming with praziquantel at regular intervals with frequencies dependent on the control program (from once monthly to twice yearly) (Larrieu et al., 2019a). Most control programs were carried out in continental south America and were able to achieve relative success with a reduction in the population of parasitized dogs and infected sheep, although some programs were discontinued due to the reemergence of the disease (Larrieu et al., 2000, 2019a). Other deployed tools include the removal of older sheep which are more likely to be infected and perpetuate transmission and post-mortem examinations to remove offals from infected sheep (Larrieu et al., 2019a). A vaccine for *E. granulosus* has been introduced by some control programmes in the last few years, with initial successes regarding vaccine efficacy (Larrieu et al., 2019b; Larrieu and Zanini, 2012). However, studies focusing on cost-effectiveness and integration with other measures of control are still pending (Larrieu et al., 2019a).

Surveillance measures include farm-based surveillance for the periodic detection and treatment of infected dogs, surveillance in humans through US-based surveys (especially in school-aged children given that the presence of active cysts indicates recent transmission) and training of primary care physicians in the use of US to stage CE (Larrieu et al., 2019a). This approach has been shown to be effective in the Rio Negro Province of Argentina. In contrast (Larrieu et al., 2011; Del Carpio et al., 2012), AE control has been less studied and implemented also due to the limited geographic distribution of the disease. Control can target foxes with periodic deworming through the use of medicated baits, and can involve surveillance in rodents to monitor for disease prevalence. Environmental surveillance using molecular tools has been proposed by some authors, however this requires further studying (Wen et al., 2019).

Introduction

Entamoeba is a tiny protozoan parasite of man and animals. The genus *Entamoeba* includes different species that infect different animals as reptiles, birds and amphibians and others. About seven species have been recovered from the gut of man. They are *E. histolytica*, *E. dispar*, *E. moshkovskii*, *E. coli*, *E. polecki* and *E. hartmanni*. *E. gingivalis* is recovered from the buccal cavity of man. *E. histolytica* is the only known pathogenic species of the human intestinal amoebae. However, some members have tendency to behave in an aggressive way and these have been incriminated in the development of pathological reactions. *E. invadens* is a parasite of reptiles and is used as a model for in vitro studies on pathogenic Entamoeba.

The pathogenic species *Entamoeba histolytica* has been identified as the cause of different health problems ranging from mild diarrhoea to invasive and extraintestinal infections. Up to 50 million persons are infected by *E. histolytica* in the world, with almost over 100,000 deaths per year (Bercu et al., 2007; Ximenez et al., 2010), especially in developing countries as Africa, India, Central and South America (Haupt et al., 2016). *E. dispar* and *E. moshkovskii* were identified as non-pathogenic amoebae. The great resemblance of the three species in morphology, makes it difficult to differentiate between the pathogenic and non-pathogenic Entamoeba by microscopic examination and adds to the complexity of the epidemiology of the disease. Previous statistics reported that 90% of cases infected with *E. histolytica* were asymptomatic, and only 10% had some symptoms (Jackson et al., 1985; Haque et al., 1999) with an overestimation of the prevalence of human intestinal amoebiasis (Diamond and Clark, 1993).

The exact identification of different species needed the use of some more sophisticated methods as Polymerase chain reaction-based assays (PCR). The studies of DNA of different organisms was the corner stone in the identification of different species within the genus *Entamoeba* (Verweij et al., 2001, 2003; Ayed et al., 2008; Ahmed et al., 2019).

Historical notes

The history of Amoeba dates back to the prehistoric era. In May 18, 1981, Kapoor published his book about Amoebic liver abscess and included a detailed description of the history of *Entamoeba* as one of the first forms of life on earth, before the evolution of man (Kapoor, 1979).

Sushruta, one of the oldest medical authority in India, mentioned the word “Antisaar” as a description of Dysentery. However, there was no clear description of any hepatic involvement (Rajasuriya and Nagaratnam, 1962).

Hippocrates (460–377 BC) was the first to introduce the medical practice based on observation and study and described dysentery as a medical problem (Americana Corporation, 1970a).

One of the famous patients in history was Alexander the Great. He was born in 356 BC and shortly after, he became an Emperor of a great and extensive Empire. During his travels to the Eastern countries with endemic disease, he became seriously ill and died later probably due to an amoebic abscess of the liver (Americana Corporation, 1970b).

Galenus (129–210 AC), observed some association between dysentery and hepatic disease (Napier, 1946) and later in the 18th century, Joaquin Pio Eguia y Lugo in Mexico, was able to connect deaths due to liver disease to dysentery (Kapoor, 1979).

The famous French leader Napoleon Bonaparte contracted bloody dysentery “thought to be amoebic in nature” in his Exile in St. Helena. The infection was common in the island. Later he was diagnosed to have a condition known as tropical hepatitis (O’Meara, 1882). The physicians who diagnosed and managed his disease were arrested and dismissed from their jobs. In the year 1821, Bonaparte’s family appointed another physician: Antomarchi to look after Bonaparte’s health. This doctor was confused of the cause of his death, if it was due to stomach cancer or as a result of liver abscess that ruptured into his stomach, as was suggested after autopsy (Chaplin, 1913). In India, Ballingall reported that there were two different types of dysentery, the acute colonitis and hepatic flux. He mentioned the method of draining liver abscesses (Ballingall, 1818; Imperato, 1980).

A post-mortem study was carried out by Annesley (1828) on 51 cases that died as a result of severe dysentery in India. He reported that 26 of them had tropical liver disease.

It is noteworthy to mention that the first parasitic amoeba (*Entamoeba gingivalis*), was discovered by Gros in 1849 (Favoreto and Machado, 1995).

Later, Lambl reported some intestinal parasites during his study on the characteristics of stools, however he didn’t mention amoeba (Lambl, 1859).

The first identification of intestinal amoebae as a cause of disease was reported by Fedor Aleksandrovich Loch in the year 1875, when he detected a moving trophozoite in the stools of a Russian patient who was suffering from dysentery (Elsdon-Dew, 1969). Later in Berlin, Robert Koch and his assistant (Koch and Gaffky, 1887) reported the presence of amoebae in ulcers of the colon of dysenteric patients. Kartulis confirmed their findings, after he reported the presence of amoebae in tissue sections of 150 dysenteric patients by microscope in Egypt (Kartulis, 1886). The same author mentioned that the amoebic liver abscess could be a complication of dysentery caused by amoebae, a condition that was called tropical dysentery at this time.

In the year 1889, Councilman and Lafleur detected amoebae in the pus from liver abscesses, and also detected that red blood cells were engulfed by amoebic trophozoites, which they called *E. dysenteriae* (Elsdon-Dew, 1969).

Experimental infections of animals were performed successfully. Kovacs infected kittens with fecal material isolated from cases with amoebic dysentery (Kovacs, 1892). His findings were confirmed later by Kruse and Pascale (Kruse and Pasquale, 1894).

The genus *Entamoeba* was established by Cosagrandi and Barbagallo in 1895 and the Latin name “*Entamoeba histolytica*” was invented by Schaudin in 1903, who suggested giving the name to the hematophagous form. He named the quadrinucleated cysts as *E. tetragena* and imagined that *Entamoeba* multiplies by some sort of budding or schizogony (Zoology, n.d.).

Walker (1908) suggested that *E. histolytica* has phases including the *tetragena* and *minuta* forms and that the development of *E. histolytica* is similar to that of *E. coli*. Elmassian called the trophozoites that come out of the quadrinucleated cysts, *E. minuta* (Elmassian, 1909).

Wenyon and O’connor and Dobell considered that the ideal condition for amoebae, is the “carrier state” in which they live in harmony with the host, feeding, growing and multiplying on the expense of the tissue of the colon (Wenyon and O’Connor, 1917; Dobell, 1919). Meanwhile, human tissue can regenerate every day, compensating any damage caused by the parasite. This was after Walker and Sellers who reported the pathogenic effect of amoebae after the deterioration of host’s natural immunity (Walker and Sellards, 1913).

The differentiation between the pathogenic *E. dysenteriae* and non-pathogenic *E. dispar*, diagnosed in asymptomatic carriers, came after studies of Brumpt (1928). This postulation was supported later by Diamond and Clark (1993).

E. moshkovskii is another species of *Entamoeba*, which has been isolated from polluted water and sewage in Moscow (Tshalaia, 1941). Later, it was called “Laredo strain” and was reported to be non-pathogenic, although morphologically identical to *E. histolytica*/*dispar*.

The differentiation between *E. histolytica*/*E. dispar*/*E. moshkovskii* is relevant by the detection of their DNA by different PCR-based tests, e.g., ssrRNA gene and other genes. Also, the Luminex PCR and multiplex PCR are considered very appropriate methods that

can differentiate more than one organism in the same test (Santos et al., 2013; Zebardat et al., 2014; Fallah et al., 2014; Gachuhi et al., 2014).

Biology and life cycle

Entamoeba is an anaerobic organism which doesn't have mitochondria (Sodeman, 1996). It has a relatively simple life cycle that has been described previously by Dobell and Laidlaw (1926), in which it alternates between two main stages, trophozoite and cyst stages. The route of transmission of *Entamoeba* species occurs initially after ingestion of mature cysts via feco-oral route and contaminated food or drink. Upon entering the host, most of these species pass through sequential developmental stages; mature cyst, metacystic trophozoites, motile pleomorphic trophozoites, precyst, cyst and metacyst stages.

When cysts are swallowed with contaminated food or drinks, they excyst, and begin to divide into small trophozoites in the gut. The pathogenic strains of amoebae may engulf RBCs into their cytoplasm, while the non-pathogenic strains feed on bacteria and the surrounding contents of the colon. The trophozoites grow and multiply by binary fission in the intestinal wall. Trophozoites are capable to adhere and lyse the epithelium of the colon and spread hematologically through the portal vein system to distant sites as the peritoneum, liver, lungs or brain, where they can initiate amoebic abscesses (Wuerz et al., 2012; Prakash and Bhimji, 2017).

Adherence to the colonic mucus layer and colonization is through the Gal/GalNAc lectin, which targets galactose and *N*-acetyl-D-galactosamine residues found on O-linked sugar side chains of mucins (Haque et al., 2003; Cornick and Chadee, 2017). Mammals that do not carry N-terminal galactose or *N*-acetyl-D-galactosamine are resistant to amoebic trophozoite adherence, providing some degree of immunity against invasive disease (Wuerz et al., 2012).

Once the parasites invade the intestinal wall, they reach the submucosa and the underlying blood vessels. From there, trophozoites travel to distant sites such as the liver, lungs or skin. These parasites are now considered to be dead-end course since they cannot leave the host and cause infection in others. It can reach different vital organs of the human body, usually the liver, but sometimes the lungs, brain, spleen, etc. However, some of trophozoites stop growing, round up and begin encystation in the lumen of the gut, a process called "precyst formation." The precyst is a spherical non-pathogenic form which is smaller than trophozoites. The precysts only undergo encystation in the colon. The signal that leads to this cyst formation is not very clear. Studies on *E. invadens* of reptiles, suggest that there may be a trigger manifested by ligation of a surface galactose-binding lectin on the surface of the parasite (Eichinger, 2001a; Stanley Jr, 2003). Also, studies showed that some Rab genes/proteins are involved in stress response, pathogenesis and virulence (Picazarri et al., 2008; Chatterjee et al., 2009; Novick and Zerial, 1997; Stenmark, 2009; Nozaki and Nakada-Tsukui, 2006). *E. histolytica* Rab gene 11B (EhRab11B) and its over expression are involved in the secretion of cysteine protease (Nozaki and Nakada-Tsukui, 2006; Mitra et al., 2007). EhRab11A is another gene which is recruited to the surface of cells and was suggested to have a role in encystation (McGugan and Temesvari, 2003).

After the organisms round up, they get rid of food vacuoles, meanwhile, their glycogen is accumulated in a vacuole besides the formation of one or more black rod-like cigar-shaped ribosomes called chromatoid bodies. Cysts also secrete thin resistant, colourless, transparent and protective cyst wall. *Entamoeba* cysts differ in size, with an average range between 12 and 20 µm (Katz et al., 1989; García and Bruckner, 1997; Clark et al., 2000). The nucleus of *E. histolytica* cyst divides twice ending in four nuclei. Cysts with one nucleus, two nuclei or four nuclei, can pass in stool, together with trophozoite stages and can contaminate food or drink. The only infective stage of them is the cyst with four nuclei.

In a study done by Chatterjee and colleagues on *E. invadens* as a model for the in vitro study of encystation of other *Entamoeba*, they reported the expression of "wattle and daub" model of formation of *E. invadens* cyst wall formation (Chatterjee et al., 2009). They described the chitin and chitin-binding lectins in the cyst wall and confirmed the presence of chitin by the use of chitin-binding stain calcofluor (Chávez-Munguía et al., 2003). They also reported that chitin only is synthesized in plasma membrane, while chitin synthases of *saccharomyces* are stored in chitosomes, which act as reservoir for its transport (Ziman et al., 1996; Cabib et al., 2001).

Cysts passed in feces can survive outside the human body in soil and in water for up to few months in favorable conditions of heat and moisture. Cysts are killed by very high as well as by freezing temperatures (American Water Works Association, 2006). Patients can catch infection in case of swallowing viable cysts in food or drink contaminated with feces of infected persons (El-Dib, 2017). In the small intestine excystation takes place in response to alkaline surroundings and intestinal enzymes forming the metacystic uni-nucleate motile trophozoites. These trophozoites finally migrate to the large intestine where they multiply, feed on mucus, bacteria and cell debris and encyst.

According to Levin's grouping for species differentiation, *Entamoeba* species can be categorized as per the number of nuclei in their fully mature cyst (Table 1) concurring with molecular techniques such as full-length 16S-like rDNA sequences (Levine, 1985; Clark and Diamond, 1997; Silberman et al., 1999).

Morphology and ultrastructure

Trophozoite

The trophozoite is the active stage of amoeba. Its size differs from one type of amoeba to another depending mainly upon the number of cytoplasmic food vacuoles and the size of phagocytosed grains. The average size of the trophozoite cell is from 20 to 30 µm with occasional diversity such as "minute form" (10 µm) or "magna form" (60 µm). Actively motile amoebae are elongated

Table 1 Members of genus *Entamoeba* inhabiting wide range of vertebrate and invertebrate species.

Category	Name of <i>Entamoeba</i> species	Other names	Geographical range	Potential hosts	Habitat	Pathogenic tendency
Species with no cyst stage	1- <i>Entamoeba gingivalis</i> (Gros, 1849)	<i>Amoeba buccalis</i> (Steinberg, 1862) <i>Amoeba dentalis</i> (Grassi, 1879) <i>Amoeba kartulis</i> (Doflein, 1901) <i>Entamoeba buccalis</i> (Prowazek, 1904) <i>Entamoeba maxillaris</i> (Kartulis, 1906) <i>Amoeba pyogenes</i> (Verdun and Bruyant, 1907) <i>Entamoeba canibuccalis</i> (Smitch, 1938) <i>Entamoeba equibuccalis</i> (Simitch, 1938) <i>Entamoeba suigingivalis</i> (Tumka, 1959)	Worldwide	Human Monkey Horse Dog Cat Pig	Oral cavity

Fig. 1 *E. histolytica* trophozoite, with irregular outline, numerous food vacuoles and single nucleus with central karyosome “arrow” $\times 1000$ original magnification.

with advancing pseudopodia (Fig. 1). A pseudopodium is a tongue-like protrusion composed mainly of ectoplasm. The trophozoite changes its direction of motion according to the microenvironmental conditions, while resting trophozoites tend to be spherical (Fig. 2) (Ludvik and Shipstone, 1970; Bansal et al., 2009).

The trophozoite's body is confined by typical plasma membrane with numerous circular openings that correspond to the mouths of micro-pinocytic vesicles, in addition to transient surface differentiations such as pseudopodia, phagocytic mouths, and a caudal uroid. Actin filaments are massed below the plasma membrane and in the pseudopodial extensions and phagocytic stoma (Gonzalez-Robles and Martinez-Palomo, 1992).

Its cytoplasm is differentiated into thin rim of clear ectoplasm and inner granular endoplasm. The granular part comprises nucleus, ribosomes, osmiophilic lipid granules and extensive vacuolar system. Electron-dense granules (EDG) were detected in trophozoites re-covered from tissue lesions. Those EDG are circular discs located near the surface of the amoebic plasma membrane and formed of a dense complex of proteins with proteolytic activities, as well as actin (Leon et al., 1997).

The cytoplasm contains great number of ribosomes and polysomes, which are dense, adjoining, ribosome-like bodies. They are arranged in the form of scattered groups of osmiophilic particles and helical bodies. Food vacuoles (from 0.5 μm in diameter to 12 μm) and lysosomes (minute vacuoles, varies from 50 to 200 nm) form the main part of the characteristic highly vacuolated system of *Entamoeba* trophozoites. Lysosomes of the amoebae differ from those of other eukaryotes in that the contained enzymes are bound to the lysosomal membrane rather than being free in the vesicular compartment, and this may give an explanation of the unique ability of *Entamoeba* lysosomal enzymes to work extracellularly (Chavez-Munguia et al., 2004).

Another number of small vacuoles is observed inside the cytoplasm of the uroid. The vacuoles are emptied by a sudden bursting of the surface or by the expulsion of the entire vacuoles into the swellings on the surface of the uroid. In actively motile trophozoites, a trail of micro-exudate is deposited on the substrate, which has cytochemical properties similar to those of the surface coat. This occurs due to the dramatic redistribution of surface components that accumulate at the uroid and are later released into the medium (Nakada-Tsukui and Nozaki, 2016).

Entamoeba species were known to have a very primitive cytoplasm, apparently lacking important organelles such as mitochondria, peroxisomes, Golgi complex and endoplasmic reticulum. In 1997, Mazzuco and his team has suggested that some of the dispersed vacuolar elements may contain the macromolecules involved in the several functions performed by the Golgi complex,

Fig. 2 Scanning electron micrograph of *Entamoeba histolytica* trophozoites; motile and resting, adhering to the human mucus covering the intestinal epithelium. (T: trophozoite; M: mucus; P: pseudopodia) (Bansal et al., 2009).

and raised the possibility that *Entamoeba* may lack molecules involved in the association of the cisternae and vesicles to form the Golgi stacks. Later on, it has been recently demonstrated the presence of a continuous endoplasmic reticulum compartment in living *E. histolytica* trophozoites (Teixeira and Huston, 2008; Perdomo et al., 2015). Moreover, the amoebic mitochondrion-derived organelle is called “mitosome” or “crypton”. The crypton lacks enzymes of oxidative phosphorylation and lacks fermentation proteins, yet it contains 2.2% of the amount of amoebic DNA. Another amoebic cytosolic structure named *E. histolytica* kinetoplastid organelle was found to contain circular DNA (Makiuchi and Nozaki, 2014).

The nucleus is about one sixth of the size of the cell body. It is bounded by double-layered membrane with numerous pores. The chromatin material is peripherally organized, and the nucleolus “endosome” is situated in the center of the nucleus. The size and distribution of chromatin is variable from cell to cell and is not a reliable diagnostic feature. Delicate achromatic fibrils radiate from the endosome to the inner surface of the nuclear membrane (Chavez-Munguia et al., 2006). *E. histolytica* trophozoites have the ability to attack the host’s cells, dissolving, killing and eating them (Ralston, 2015).

Mature cyst

Mature cysts are rounded or slightly oval bodies 8–20 µm in diameter. They are uni/multinucleated with condensed chromatin attached to nuclear membrane, contain big vacuoles, ribonucleoprotein helices and densely packed chromatoid bodies in the cytoplasm (Fig. 3). An apparently smooth wall surrounds it, 125–150 nm thick. The cyst wall is composed of fibrillar material, which forms a tight mesh (Aguilar-Diaz et al., 2010).

In early cystic stages, the chromatoid bodies arise by aggregation of ribosomes forming polycrystalline masses with blunt, rounded, irregular or splinter like ends (Fig. 3). In maturing cysts, these crystalline masses fragment into separate particles, and the classical chromatoid body tends to disappear. This phenomenon hypothesizes that the large chromatoid bodies formation is a manifestation of special parasite-host adaptive mechanism; ribonucleoprotein is synthesized under favorable conditions, crystallized in the resistant cyst stage, and dispersed in the newly excysted amoebae, thereby enabling them to establish themselves in a new host by a period of quick growth (Barker and Svihla, 1964). Large carbohydrate reserves in the form of glycogen are present in the precyst stages, and then disappear gradually as the cyst goes to maturity. Similarly, the cyst wall precursors appear in the cytoplasm as vesicles with filamentous hyaline content of intermediate density. Rapidly the secreted material forms tough mesh-like cyst wall around the cell (Fig. 4), the nucleus starts to divide, and the rest of organelles disappear while the cyst proceeds to maturity (Chávez-Munguía et al., 2003; Mehlhorn, 2005).

Taxonomy and important species

Taxonomic hierarchy:

Kingdom: Protozoa

Phylum: Protozoa

Subphylum: Sarcodina

Superclass: Rhizopoda

Class: Lobosa

Order: Amoebida

Family: Entamoebidae

Genus: *Entamoeba*

Species: *Entamoeba histolytica* (Schaudinn, 1903)

Fig. 3 *E. histolytica* pre-cyst, with rounded boundaries, two nuclei and thick chromatoid body “arrow”. ×1000 original magnification.

Fig. 4 SEM showing the smooth surface, spherical shape and small size of the cyst. Insert shows a magnification of a hole in the surface, where overlapping fibers that resemble chitin-fibers in other organisms are observed (Aguilar-Diaz et al., 2010).

Entamoeba species of medical importance to man

Entamoeba dispar

Entamoeba dispar gets its importance from its morphological resemblance to *E. histolytica*, however, it has its famous reputation as a non-pathogenic species of *Entamoeba*. Recent studies showed that it can produce some pathological lesions (Espinosa-Cantellano et al., 1997, 1998). *E. dispar* was reported as a cause of non-dysenteric colitis (Costa et al., 2006) or amoebic liver abscess (Ximenez et al., 2010). Graffeo et al., reported a case of enteritis caused by *E. dispar*, in a patient that lives in a non-endemic area. Diagnosis was done by the identification of DNA (Graffeo et al., 2014). After studying many samples from amoebic liver abscesses, Olivera et al., reported that *E. dispar* began to show a different facet (Oliveira et al., 2015). *E. histolytica* was believed to show two different groups by isoenzyme electrophoresis; a pathogenic and a non-pathogenic form of the parasite. This fact was used to explain why infection could be asymptomatic in some cases in the past (Sargeant et al., 1978). DNA analysis of the two different species was the proper method for their identification into *E. histolytica* and *E. dispar* (Diamond and Clark, 1993). It was estimated by WHO that *E. histolytica/dispar* infects around 12% of world populations, putting into consideration that *E. histolytica* accounts for about 1% of infections (World Health Organization, 1997). Hematophagy is always associated with *E. histolytica* infection. Although *E. dispar* is sometimes pathogenic, but without tissue invasion (Van Den Broucke et al., 2018).

Entamoeba moshkovskii

E. moshkovskii was recovered from wastewater in the year 1941 in Moscow, Russia by Tshalaria (Van Den Broucke et al., 2018; Scaglia et al., 1983) and thought to be free living. The first human isolate of this parasite was known as “Laredo strain” of *E. moshkovskii* when identified in Laredo, Texas in the year 1991 from a case who complained of diarrhoea, epigastric pain and weight loss (Heredia et al., 2012). The identified strain was called *E. histolytica* Laredo strain and it was found to share some features similar to *E. moshkovskii*, as both organisms can grow in culture at room temperature, resist the osmotic shock and could be resistant to the anti-amoebic drug emetine (Fotedar et al., 2007a). *E. moshkovskii* resembles *E. histolytica/dispar* in morphology (Fotedar et al., 2008). Human cases have been detected by the identification of DNA of the organism (Ali et al., 2003). Scientists examined 109 preschool children in Bangladesh and could detect 15.6% positive for *E. histolytica*, 35.8% positive for *E. dispar* and 21.1% positive for *E. moshkovskii*. This result shows that man acts as a host for this parasite (Ali et al., 2003).

E. moshkovskii was reported in Malaysia, India, Bangladesh, Turkey, Tanzania, Australia and North America, affecting all ages and genders (Shimokawa et al., 2012).

Experimental studies in Bangladesh, showed that *E. moshkovskii* was pathogenic to the mice, and was manifested with diarrhoea in children. Scientists reported the association of human infection with diarrhoea, weight loss, abdominal colic and bloody stool (Heredia et al., 2012).

Entamoeba coli

E. coli is a common non-pathogenic, commensal species that lives and multiplies in the colon and have a similar life cycle as *E. histolytica*. It is considered the largest member of the genus. The trophozoite is about 15–50 μm, with an average of 20–30 μm. *E. coli* has a sluggish movement, with slow formation of 3–5 pseudopodia that moves the parasite in its place with non-progressive motility. However, trophozoites stay immobile mostly with an almost rounded shape. Its cytoplasm is hyaline and granular, when

seen with microscope in fresh mount, it may have a number of short blunt pseudopodia. It contains many food vacuoles containing bacteria, starch and yeast. Sometimes the trophozoite may have food vacuoles that contain some smaller parasites e.g., *Giardia*, or other small protozoa, besides fungi e.g., *Sphaerita* species (Hamad et al., 2017). Scientists claim that *E. coli* has the potential to fight other organisms for nutrition by phagocytosing them, however they never invade the mucosal layers or produce any lesion. Nucleus of *E. coli* is 5–7 µm, lined with irregular coarse chromatin granules, eccentric karyosome which gets attached to the nuclear membrane with fine threads. Cyst of *E. coli* is globular, measures from 10 to 35 µm with a thick, double layered cyst wall. Usually the mature cysts are smaller in size and contains 8 nuclei, however sometimes it is possible to see a cyst with 16 or even 32 nuclei “supernucleate cysts” (Atlas, n.d.). Some immature cysts, with one nucleus may have a large glycogen vacuole, that pushes the nucleus to one side of the cyst. This glycogen vacuole disappears later with maturation of the vacuole. Thin chromatoid bodies with tapering ends could be seen inside the cyst (Atlas, n.d.).

Entamoeba hartmanni

Entamoeba hartmanni belongs to the four-nucleated cyst-forming amoebae, formerly known as “the small race of *E. histolytica* or *E. histolytica sensu stricto*” (Von Prowazek, 1912). It has been detected in many stool specimens worldwide, possessing a similar life cycle to that of *E. histolytica* but with no histolytic or hematophagous characteristics (Burrows, 1957).

The main feature to differentiate *E. hartmanni* from pathogenic *E. histolytica* is the small-sized trophozoites, which may reach (3–10 µm) in diameter. However, the distribution of peripheral chromatin on the inner nuclear membrane has added another significant difference. Since *E. hartmanni* can show many patterns of chromatin aggregation such as uniform distribution in ~2/3 of samples, thick large or small masses in ~1/6 or mostly discrete compact areas of chromatin aggregation, closer to that of *E. coli*. Accordingly, it forms small-sized cyst (3.8–8 µm) with one-to-four nuclei of relatively small diameter. They have characteristic chromatoid bodies with smooth, rounded edges, varying in number and diffuse glycogen stores (Burrows, 1964).

Laboratory diagnosis is achieved by looking for the above morphological features of trophozoite and cyst in wet/or iodine stained stool preparations. *E. hartmanni* has been successfully cultivated and surprisingly, it was indistinguishable from *E. histolytica* on both morphology and size (~13.2–15.6 µm) (Sarkisian, 1957).

The high endemicity of *E. hartmanni* in tropical and sub-tropical rural areas plays an important role in the misdiagnosis of *E. histolytica*, which lead to increased false positive results (Matey et al., 2016).

Though all the data mentioned *E. hartmanni* as non-pathogenic commensal, yet it has proven recently that it may cause limited to mild level of pathogenicity. It was incriminated as a cause of diarrhoea in AIDS cases (Rolston et al., 1986) and as a causal agent in reactive arthritis individuals, which was dramatically improved after the application of metronidazole (Schirmer et al., 1998). Finally, *E. hartmanni* colonization was associated with mild to severe diarrhoea, which was diagnosed by molecular assays (Matsumura et al., 2019).

Entamoeba gingivalis

E. gingivalis was the first identified human amoeba (Favoreto Jr. and Machado, 1995). It inhabits the buccal cavity, gingiva, and the periodontal pockets (Prieto-Prieto and Calvo, 2004; Bonner et al., 2014) as an opportunistic protozoon (Lyons et al., 1980). It is common in about 95% of cases with gum disease, but not in healthy gums (Kofoed et al., 1929; Trim et al., 2011). This type of *Entamoeba* has a trophozoite stage only (20–150 µ), and no cyst forms, therefore the mode of infection is direct from mouth to mouth during kissing or the use of the same contaminated food utensils. Trophozoites have active pseudopodia and numerous food vacuoles containing nuclei of polymorphonuclear leucocytes, RBCs and bacteria (Bonner, 2013). The organism could be visualized by light microscope after preparing a direct smear from the gingiva at room temperature.

Entamoeba polecki

This intestinal amoeba acts as a parasite of pigs and monkeys. In the year 1912, Von Prowazek detected the parasite in Czechoslovakia in the stools of two cases from Kampuchea. Although human infection has been reported, clinical symptoms are not known due to rarity of cases (Smith, 2019).

Entamoeba polecki is world-wide in distribution, however most of the reported cases came from developing countries and sporadic cases occur in developed countries. *E. polecki* was reported in 19% of the population of Papua New Guinea and was also reported as endemic in Cambodia, Venezuela and Vietnam. However, there were infections in refugees from South East Asia living in France, Minnesota and Venezuela (Smith, 2019).

Zoonotic Transmission could be the source of infection probably from pigs or monkeys (Wiwanitkit, 2004). Human infection with this parasite is mostly asymptomatic, but some non-specific symptoms as diarrhoea, nausea, vomiting, fever, abdominal pain and weight loss may be accompanied with this infection. It is recommended to treat cases with *E. polecki* with metronidazole (Smith, 2019).

The cyst is between 12 and 15 µm and are spherical or subspherical and the nuclear peripheral chromatin is generally distributed non-uniformly. As the morphology of *E. polecki* resembles those of *E. coli* and *E. histolytica*, detection of mature cysts is required for proper diagnosis of *E. polecki*. DNA was extracted from infected feces and used successfully to amplify part of the amoeba ssrRNA (Verweij et al., 2001). There are four subtypes of *E. polecki* from “ST1 to ST4”, all have been recovered from human cases. Although

they are exclusively parasites of primates, ST4 is the most common subtype in man denoting a possible potential zoonotic transmission (Stensvold et al., 2011).

Metronidazole has been used to treat cases known to be infected with *E. polecki* to avoid its possible pathogenicity (Lyons et al., 1980; Wiwanitkit, 2004). Combination of Metronidazole and diloxanide furate is also recommended in treatment of infections (Solaymani-Mohammadi and Petri, 2006).

Entamoeba invadens

This species of *Entamoeba* infects reptiles e.g., snakes and lizards with severe mortality that may reach up to 100%, although turtles and crocodiles tend to be asymptomatic carriers (Segovia-Gamboa et al., 2010). Transmission occurs by feco-oral route. Its life cycle resembles that of *E. histolytica*. The resistant cyst stage rich in carbohydrates is the infective stage (Eichinger, 2001b), and the motile active trophozoite stage, causes the pathologic effect of the parasite (Chia et al., 2009).

Because of similarity in their life cycles, this parasite, as previously stated, is used as a model for studying the development and encystation in vitro in order to understand some missing points in *E. histolytica* (Ehrenkauser et al., 2013), particularly *E. invadens* is the only *Entamoeba* species that can encyst in vitro (Welter et al., 2017). Trophozoites of *E. invadens* move in amoeboid movements, but they round up under stress. Cysts, are smaller, rounded and quadrinucleated. The cyst has a homogenous unlayered cyst wall (Chatterjee et al., 2009), which resists extreme environmental conditions such as desiccation, heat and detergents (Smith, 2019).

Pathophysiology and clinical picture

The reason why *E. histolytica* acts in a virulent way is still a matter of debate. Some patients may have asymptomatic infection, while others develop more serious attacks as acute colitis or even extraintestinal disease. The environment, the host's immune status as well as the genetic susceptibility, age and gender, all were thought to have roles in the severity of the disease (Ximenez et al., 2010; Jackson et al., 1985; Bernin et al., 2014).

Recent studies have been done on how the intestinal flora can influence the pathogenicity of *E. histolytica* (Dolabella et al., 2012; Furst et al., 2002) and how they can influence the adhesion capacity and the cytopathic effects of *E. histolytica* trophozoites (Galván-Moroyoqui et al., 2008). These trophozoites have more power of invasion of the colonic epithelium as a result of the proinflammatory cytokines produced in the presence of bacterial flora (Galván-Moroyoqui et al., 2008). They subsequently spread hematologically through the portal vein system to distant sites such as the peritoneum, liver, lung, or brain (Wuerz et al., 2012; Prakash and Bhimji, 2017).

Certain enzymes have been incriminated in the process of virulence and invasiveness. Glucosidase, *N*-acetylgalactosaminidase and *N*-acetylglucosaminidase are enzymes that can help to remove branched polysaccharides from mucin cells. This process allows the trophozoites to penetrate the epithelial wall of the colon after degradation of the protective mucous barrier (Ximenez et al., 2010; Prakash and Bhimji, 2017; Haque et al., 2003; Cornick and Chadee, 2017; Bernin et al., 2014; Thibeaux et al., 2013). Trophozoites that can't adhere to the mucosa of the gut of the hosts are those which do not have N-terminal galactose or *N*-acetyl-D-galactosamine. They are eventually incapable of causing invasive disease (Prakash and Bhimji, 2017).

Secretory mucosal immunoglobulins have essential role in the immune response, especially IgA produced in the lamina propria as a protective element of the gut mucosa. Mucosal anti-Gal/GalNAc lectin IgA was reported to prevent the amoebic colonization and penetration of the gut mucosa (Haque et al., 2003, 1990; Quach et al., 2014).

The pathophysiology caused by amoebic trophozoites in tissue of the host is not very clear, however host cells are killed by the amoebic trophozoites using two main mechanisms, trophocytosis and phagocytosis. Trophocytosis is a process during which *Entamoeba* bites distinct fragments of the host cell. This biting process is called "amoebic trophocytosis or nibbling." After attaching to host cells, amoebae bite off and ingest distinct host cell fragments, and this contributes to cell killing (Ralston, 2015).

Phagocytosis usually depends on three consecutive actions; adherence, lysis of host cell, and phagocytosis. The contact-dependent attachment is moderated by the amoebic Gal/GalNAc adherence lectin. *Entamoeba* host cell is thought to induce host cell apoptosis, followed by phagocytic clearance of human C1q protein-labeled apoptotic cell. Limitation of the inflammation and evasion of the immune system are important outcomes from these processes (Cornick and Chadee, 2017; El-Dib, 2017). Host cell viability is an important factor for the occurrence of trophocytosis and phagocytosis. Ralston (2015) incubated amoebic trophozoites with living host cells and reported that the amoebae ingested the living cells by trophocytosis, while the dead cells were ingested by phagocytosis (Ralston, 2015).

Asymptomatic infection

Some infections are not manifested by symptoms and these are diagnosed accidentally.

Approximately 90% of *Entamoeba* infections are asymptomatic (Haque et al., 2003; Stenmark, 2009; Cheepsattayakorn and Cheepsattayakorn, 2014).

Acute diarrhoea

Acute diarrhoea is the second cause of death due to parasitic disease in low income countries (Kotloff et al., 2017). It may cause death among children under 5 years (Liu et al., 2016). Acute diarrhoea is sometimes associated with vomiting, colic and fever. It is considered a mild symptom of amoebic colitis.

Amoebic colitis

Amoebic colitis is usually mild in most of the cases with subacute onset and mild diarrhoea. However, it could be manifested by severe dysentery i.e., with mucous and blood in stool, colic, fever, and tenesmus (Haque et al., 2003). The incubation period after ingestion of the infective stage also differs from 7 to 28 days. The mild infection may be abdominal colic, diarrhoea "3–8 motions/day", or dysentery, flatulence and tenesmus. In severe infection there may be fever with tenderness of the abdomen, vomiting, diarrhoea "10–20 motions/day" and loss of weight (El-Dib, 2017). If diagnosis is delayed, the case may develop to a fulminating necrotizing colitis, which is fatal in 40% of patients (Haque et al., 2003; Bradly et al., 2015; Misra et al., 2006). Fortunately, this complication is not common. In those with concomitant liver abscess, mortality increases to 89% (Ortiz-Castillo et al., 2012; Takahashi et al., 1997). Patients look toxic, with fever, bloody diarrhoea, and signs of peritoneal irritation (Bradly et al., 2015; Moorchung et al., 2014).

A condition as toxic megacolon could develop as a result of corticosteroid use and the patients need surgical intervention when they don't respond to antiamoebic therapy (Moorchung et al., 2014; Shirley et al., 2016).

Toxic megacolon

This rare complication occurs in about 0.5% of infections. It is defined as segmental or total dilatation of the external diameter of the colon to more than 6 cm, accompanied by systemic toxicity. This type of infection may end by fatal colon perforation (McGuiness and Leder, 2019).

Ameboma formation

The formation of an ameboma is another uncommon manifestation that may occur in amoebic colitis. Ameboma is a localized hyperplastic granulation tissue that occurs in the cecum or ascending colon. It tends to present with pain and swelling in the right iliac fossa, or with symptoms of bowel obstruction (Misra et al., 2006). It could be misdiagnosed with neoplasms, tuberculosis or abscess and could be properly diagnosed by colonoscopy and histopathology (Fig. 5A and B) (Misra et al., 2006; Moorchung et al., 2014). Amebomas may be single or multiple. The common locations are in the coecum, caecal appendix and sigmoido-rectal areas. However, may also occur in other sites, although very rare. Lomeli et al. (2016), reported an ameboma in the ampulla of Vater, extending to the pancreas as well as in the colon. The lesion shows extensive chronic reaction with the presence of *E. histolytica* trophozoites, necrotic tissue and fibrosis. Ameboma formation has been generally associated with untreated or partially treated amoebic colitis (Misra et al., 2006).

Fig. 5 (A) Colon with an indurated grey lesion of 4 × 5 cm (Black arrow), and an intense inflammatory reaction. (B). Microphotography (10 ×) of a PAS stained tissue showing *E. histolytica* trophozoites (Black arrow) (Lomeli et al., 2016).

Extraintestinal infection

Amoebic liver abscess

After penetrating the colonic wall and reaching the portal veins, *E. histolytica* trophozoites find accessibility to the liver parenchyma. They take 2–4 weeks to develop amoebic liver abscess. Patients usually present with fever and pain in the upper abdominal quadrant (Wuerz et al., 2012; Prakash and Bhimji, 2017; Haque et al., 2003). Around 50% of cases may complain of chronic diarrhoea, abdominal pain and weight loss. In some cases where the abscess is near the diaphragmatic surface, the patient may develop right pleural effusion with subsequent cough and right chest pain (Haque et al., 2003). Around 40% complain of dysentery, leukocytosis and elevation in the liver enzyme alkaline phosphatase (Wuerz et al., 2012; Prakash and Bhimji, 2017). Usually amoebic abscess is solitary, however multiple abscesses have been reported (Lomeli et al., 2016; Nattakom et al., 2001).

Amoebic liver abscess is an important cause of space-occupying lesions of the liver, mainly in tropical regions. Prompt recognition and appropriate treatment lead to improved morbidity and mortality (Brallita, 2019).

Hemolytic uremic syndrome (HUS)

Another severe complication of extraintestinal invasion by *E. histolytica*, is manifested by kidney injury which could lead to kidney failure, anemia and thrombocytopenia (Exeni et al., 2018). The kidneys are affected by microangiopathic thrombi resulting in long-term pathology. Other organs such as the intestine, central nervous system, and heart may also be affected.

E. histolytica and metronidazole are incriminated in developing a HUS in a 9-year old child (Mele et al., 2014) and *E. histolytica* was identified as a cause of HUS in a 11-year-old child that necessitates hemodialysis (Malaki, 2014).

Diagnosis of amoebic infection

Laboratory diagnosis of Amoebiasis

Entamoeba species are diagnosed directly either by identifying cysts or trophozoites in fecal specimens or by visualizing parasitic stages in biopsy specimens of intestinal mucosa (Fig. 5B). Immunological and molecular-based diagnostic methods should also be used simultaneously (Heredia et al., 2012; Cavagnaro et al., 2006; Sheehan et al., 1979).

Direct coproscopic examination

For over 100 years, microscopy remained the most frequently performed laboratory procedure worldwide, by which almost all intestinal parasites can be detected at the same time. It is considered as a screening method for *Entamoeba* species when performed by an experienced microscopist, especially in low-income settings (Nunez et al., 2001; Tanyuksel and Petri, 2003).

Grossly, formed stool is likely to contain cysts, whereas watery or dysenteric stool usually harbors trophozoites. Direct wet mount preparations help to demonstrate the motility of trophozoites and the internal structure of cysts, if temporary stains are used. However, it is well known that trophozoites are fragile and can rapidly disintegrate soon after passage unless examined or immediately preserved, which is believed to outweigh the limited mobility information, gained by examining the fresh specimens (Garcia and Bruckner, 1997).

Various preservatives are available. They should be paired with the appropriate concentration procedure and permanent staining to give the best results (Lebbad and Svard, 2005; Jensen et al., 2000). Laboratories worldwide used numerous successful staining methods such as Wheatley's trichrome, iron hematoxylin, Giemsa, Wright's, Chlorazol Black E and iodine-trichrome stains. Even though they are tedious and time-consuming, yet they increase sensitivity of microscopy, provide a permanent record, and allow for subsequent consultation if unusual morphologic characteristics are detected (Tan et al., 2010).

The principal limitation of this method is its inability to differentiate closely related *Entamoeba* species and heterogeneity within species (Petri et al., 2000). In addition, the intermittent shedding of intestinal stages, which necessitate examination of three successive stool samples to increase the sensitivity by 23%, and low detection threshold in light infections all add to the limitation of microscopy (Nunez et al., 2001; Hiatt et al., 1995).

Immunodiagnosis

Serology-based diagnosis tools can be divided into two categories: antibody-detection assays and antigen-detection assays.

Antibody detection

Variety of assays are commercially available for detection of *Entamoeba* species antibodies in serum to detect cases of chronic carriers and extra-intestinal invasive species infected patients. They include indirect hem-agglutination and latex agglutination (least sensitivity and specificity), immuno-electrophoresis, counter immuno-electrophoresis, the amoebic gel diffusion test, immuno-diffusion (time-consuming), indirect immunofluorescence assay, while enzyme linked immunosorbent assay (ELISA), proves to be the best way for antibody detection (Fotedar et al., 2007a; Caballero-Salcedo et al., 1994).

Serological diagnosis of *Entamoeba* infection is not beneficial to distinguish past from current infection especially in endemic areas. However, it may be helpful in industrialized nations, where feco-oral infections are not common (Ohnishi and Murata, 1997). In addition, it is still subjected to false positive results due to cross reactivity and negative reactions because of delayed

appearance of antibodies in blood, which may take around 7–10 days to be detected (El-Dib, 2017; Zengzhu et al., 1999; Blessmann et al., 2002; Haque et al., 2010).

Antigen detection

Antigen detection assays in sera have proved to be very useful in the diagnosis of *Entamoeba* species. More specific detection can be achieved using commercially available antigen detection kits, which use monoclonal antibodies against soluble Gal/GalNAc-specific lectin (adhesin molecule) released in the whole blood/serum/stool samples from suspected patients. Although antigen testing is both rapid and technically simple, yet it is more sensitive in areas with high prevalence of *E. histolytica* rather than non-endemic setting (Stark et al., 2008). No specific antigen tests are available for the differentiation (Haque et al., 2000).

One of the available assays is immunochromatographic card test (ICT), which plays an important role in the diagnosis, as it is fast, cost-effective, sensitive and does not need special equipment or experienced personnel. Triple stool immunochromatographic assays is the first convenient alternative enzyme immunoassay for the simultaneous detection of *Entamoeba histolytica*/*E. dispar*, *Giardia lamblia* and *Cryptosporidium parvum* in fresh or frozen fecal samples (Fig. 6) (Garcia et al., 2000; Banisch et al., 2015; Swierczewski et al., 2012).

It is not a method of choice for the final diagnosis due to its inability to differentiate between pathogenic and non-pathogenic species of *Entamoeba*. However, it provides adequate sensitivity and specificity in outbreaks, screening proposals and for massive assay in endemic areas where a large number of samples must be analyzed or as complementary test for individual diagnosis (Goñi et al., 2012).

Molecular diagnostic techniques

Several recent protocols for detection of *Entamoeba* species are now available, which include conventional PCR, nested PCR, and real-time PCR. *Entamoeba* PCR assays target different genetic loci, but the subunit ribosomal RNA gene has been used most often for all *Entamoeba* species due to its multi-copy nature and high analytical sensitivity (Fotedar et al., 2007b).

In an effort to improve the PCR protocol, molecular assays were developed for specific discrimination between different *Entamoeba* species and/or simultaneous detection of other protozoan species in a single assay, such as Duplex PCR, Multiplex real-time PCR (Fig. 7) and Luminex PCR assay. In addition, these closed-tube assays minimize the potential for cross-

Fig. 6 RIDA® QUICK *Cryptosporidium*/*Giardia*/*Entamoeba* Combi ICT showing three bands. From left to right: crimson band “control”, green band “*Entamoeba* positive”, red band “*Giardia* positive” and blue band “*Cryptosporidium* positive”.

Fig. 7 Detection limits of *Entamoeba* sp. using Real-time PCR. Real-time PCR showed the detection limits of each *Entamoeba* sp. to be as low as 0.625 cysts (Lau et al., 2013).

contamination, reduce the time needed and provide highly accurate quantitative data (Blessmann et al., 2002; Verweij et al., 2004). On the other hand, these techniques are still of high cost, need experience and have been postulated that they show more sensitivity in detection of samples with trophozoites than cysts (Fotedar et al., 2007b; Haque et al., 1998).

Diagnosis of amoeboma

Suspected cases are diagnosed after histopathological examination of specimens taken by endoscopy. As stated before, amoebomas could be single or multiple, appears tumour-like with irregular friable surface and necrotic bleeding tissue.

Diagnosis of extraintestinal lesions

Diagnosis is often needed after suspected clinical picture. It is initiated with imaging techniques to determine the presence of abscess in the liver, lungs, brain, etc. If indicated, aspiration preferentially at the periphery of the lesion is performed under US or CT scan for culture, DNA and/or antigen detection. Aspiration is also recommended in cases where the abscess is located in the left lobe of the liver, or in cases with severe pain or elevated diaphragm (Kapoor, 1979).

Treatment

At the days of Hippocrates, curing an abscess was done by draining its contents (Americana Corporation, 1970a). Hippocrates stated that "Desperate diseases need desperate remedies" (Anon, 1959) and advised physicians to assist Nature's ways to heal the sick.

Bloodletting by leeches was a common method for treatment of many diseases. However, laxatives and mercurial purgatives were also commonly used. Meanwhile some surgical practices as trocar aspiration or open drainage were also known in the 19th century (Ballingall, 1818). This technique was adopted when the author noticed a case of an officer in Madras, India who had been shot in his liver, which was infected with an abscess. This shot drained the abscess leading to complete cure (Ballingall, 1818).

The use of quinine was also tried in few such cases (Morehead, 1856). Ipecacuanha was a famous herbal therapy for the "bloody flux, or dysentery" since the 16th century among natives in Brazil. Rogers got the use of Ipecacuanha back replacing other unsatisfactory methods. He also reported the isolation of alkaline emetine from Ipecacuanha and mentioned its amazing effect on amoebic dysentery and liver abscess (Rogers, 1912).

It is recommended that all infections with *E. histolytica* including the carriers should be treated. This is going to prevent the development of invasive disease, but also will decrease the spread of infection (Bradly et al., 2015).

Paromomycin, a luminal antibiotic can eliminate cysts of *E. histolytica* from the gut lumen, however metronidazole and tinidazole which mainly affect the trophozoite stages, are important agents against invasive amoebiasis (Haque et al., 2003; Bradley et al., 2015).

Nitroimidazoles e.g., Metronidazole and those with longer half-lives, such as tinidazole, secnidazole, and ornidazole, allow for shorter treatment periods and tend to be better tolerated. After a 10-day course of a metronidazole, paromomycin should be given to assure that the luminal parasites are cleared and prevent relapse (El-Dib, 2017; Liu et al., 2016). It has been shown that 40–60% of patients have persistent intestinal parasites after treatment with only nitroimidazole. Second line luminal agents include diiodohydroxyquin and diloxanide furoate (Haque et al., 2003; Liu et al., 2016).

Treatment of asymptomatic infection constitutes a real medical conflict, to treat or not to treat. McGuinness and Leder as well as the current US treatment guidelines recommend treatment of asymptomatic infection, as there is always a potential risk of causing an invasive disease or spread to family members (McGuinness and Leder, 2019).

The recommended protocol approves the administration of Iodoquinol 650 mg PO three times a day for 20 days in adults, while children are given: 30–40 mg/kg/day PO in three divided doses for 20 days OR paromomycin 25–35 mg/kg/day PO in three divided doses for 7 days OR diloxanide furoate 500 mg PO tds. For 10 days in adults and 20 mg/kg/day PO in three divided doses for 10 days in children (McGuinness and Leder, 2019).

Treatment of cases infected with other species of *Entamoeba* represents a real challenge. It could be better to treat cases for the potential risk of development to an invasive disease as well as spread to the community (McGuinness and Leder, 2019).

As stated before, *E. dispar* has the potential to behave in an invasive way, so infected cases are treated with luminal amoebicide e.g., Paromomycin 30 mg/kg/day for 10 days in three divided doses (Tengku and Norhayati, 2011).

Control of *E. polecki* infection as a newly emerging zoonosis is important. Although cases may be asymptomatic, yet treatment with metronidazole is necessary to avoid possible pathogenicity (Smith, 2019).

Cases with *E. moshkovskii* in Tropical areas are treated with antiparasitic therapy (Fotedar et al., 2007a). Nitroimidazole and luminal drugs are paired together when gastrointestinal symptoms are present (Fotedar et al., 2007b).

Epidemiology

The global statistics on the prevalence of *E. histolytica* infection indicates that 90% of infected cases are asymptomatic while the other 10% develop clinical manifestations. It has been estimated that up to 50 million people in the world, particularly in developing countries are affected by *E. histolytica*. It is estimated that infection may reach up to 50% in developing countries e.g., Africa, Central

and South America and some Asian countries (WHO, 2009). WHO stated that factors as poverty, bad sanitation, lack of clean water and lack of knowledge can affect spread of infection (Lo et al., 2014). In industrialized countries, infection is detected among travelers, institutions, homosexual males and HIV infected persons (Khairdar et al., 2007).

The disease could be responsible for over 100,000 deaths per year (Bercu et al., 2007; Ximenez et al., 2010). Although all the deaths could be due to invasive *E. histolytica* infections, Recently *E. dispar* and *E. moshkovskii*, morphologically identical species, have been detected in individuals inhabiting endemic areas of amoebiasis and could be contributing to the prevalence percentages. Thus, the reclassification of *E. histolytica* into the three morphologically identical yet genetically different species has further added to the complexity of the epidemiology of amoebiasis since they cannot be differentiated by microscopy most commonly used for diagnosis particularly in tropical countries where resources are limited (Ali et al., 2003; Shimokawa et al., 2012).

However sometimes infection is severe due to invasion of the colonic epithelium or extraintestinal tissues by virulent species *E. histolytica*. Patients may exhibit abdominal pain with cramps, diarrhoea which could contain blood or mucous (Haque et al., 2003).

Amoebic liver abscess is the most common extraintestinal or invasive amoebiasis, that occurs due to transmission of the organism by hematogenous route, followed by pulmonary, pericardial and brain abscesses (Haque et al., 2003).

Epidemiology of amoebiasis is affected by some factors, the most important of which is that man is the only host of infection with no animal reservoir hosts. Asymptomatic carriers constitute the main source of infection, passing cysts in feces. Cysts are directly infective and survive long periods in the environment resisting chlorination. Disease transmission occurs due to ingestion of contaminated food and/or water. Sexual transmission has been mentioned among male homosexuals as another mode of infection (Stark et al., 2008).

Acknowledgments

The parasite

Morphological and anatomical characterization

Fascioliasis is a freshwater snail-borne zoonotic disease caused by two species of *Fasciola* (Trematoda: Fasciolidae): *Fasciola hepatica* distributed almost worldwide and *F. gigantica* restricted to parts of Africa and Asia (Mas-Coma et al., 2009a).

These species are leaf-shaped, with two suckers in a conelike anterior extension of the body and a broadly pointed posterior end. In size, *F. gigantica* (slightly more than 50 mm) is almost the double length of *F. hepatica* (up to 29 mm), and in shape it is more elongate and narrower, with lateral walls tending to be parallel, and with nonexistent or less marked shoulders of the cephalic cone (Fig. 1A and B).

Their digestive system includes a patent pharynx and two long highly ramified intestinal caeca reaching the posterior end. The genital hermaphroditic system comprises (i) a male system with two branched testes in longitudinal tandem within the second and third fourths of the body, and a prominent cirrus pouch, containing a spined cirrus protrusible through a post-bifurcal genital pore, and (ii) a female system with a pretesticular, dextral branched ovary, numerous small vitelline gland follicles extending bilaterally up to the hind body, and a short uterus between the ovary and caecal bifurcation.

The eggs are ovoid, yellowish, operculated, and nonembryonated when laid. Egg length/width in *F. hepatica* measure 73.8–156.8/58.1–98.1 µm in animals and 100.6–162.2/65.9–104.6 µm in humans, whereas in *F. gigantica* they are of 130.3–182.8/74.0–123.6 µm in animals and 150.9–182.2/85.1–106.2 µm in humans (Fig. 1C and D) (Valero et al., 2009; Mas-Coma et al., 2014a).

The measurements of the two species overlap, although given features allow to classify specimens in populational analyses (Periago et al., 2006). Given that fasciolids grow inside the biliary canals and morphometrics vary according to age and host species, studies and comparisons should be made only with other fasciolid populations infecting the same host species (Valero et al., 2005). Moreover, intermediate forms appear in overlap areas of Africa and Asia, due to hybridization of both *Fasciola* species (Periago et al., 2008; Afshan et al., 2014a; Ahasan et al., 2016).

Molecular and genetic characterization

A study on the origin of *F. hepatica* and *F. gigantica* and their subsequent worldwide evolution was made by Mas-Coma et al. (2009a), based on palaeobiogeographical and evolutionary data of their mammal host species and lymnaeid vector species, by considering parasite-host relationships in crucial aspects as specificity, pathogenicity and immunity, developmental requirements

Fig. 1 Fasciolid adults and eggs: (A) adult stage of *Fasciola hepatica* from cattle in the Northern Bolivian Altiplano; (B) adult stage of *F. gigantica* from zebu of Bobo Dioulasso in Burkina Faso; (C) egg of *F. hepatica* from a child in the Northern Bolivian Altiplano; (D) egg of *F. gigantica* from zebu of Bobo Dioulasso in Burkina Faso. For measurements, see text. Photographs S. Mas-Coma.

(e.g. temperature thresholds) and present geographical distribution and ecological requirements of the respective specific lymnaeid vector species of both fasciolids in the five continents. The long-time evolutionary scenario of fasciolid global spread up to the present was defined by distinguishing two periods: (i) a long pre-domestication million-year period from their respective palaeobiogeographical origins and subsequent evolution until human arrival; and (ii) a shorter post-domestication 12,000-year period from the beginning of the domestication of herbivore mammal species, along the archaeological knowledge on year thousands during which these domesticated animals were moved or transported by humans throughout until defining the present day scenario (Mas-Coma et al., 2009a). This evolutionary scenario offers a framework for the interpretation of the results of genetic studies.

According to this framework (Mas-Coma et al., 2009a), the fasciolid ancestor may be found in an ancient liver fluke form infecting old Artiodactyla in Africa during the early Oligocene when the first pecoran radiation occurred. The origin of *F. gigantica* was probably the result of an adaptation to bovids (Alcelaphinae, Reduncinae, Bovinae), resulting in an explosive radiation during the early Miocene, in the warm, eastern Africa, where the lymnaeid snail *Radix natalensis* assured the transmission. The origin of *F. hepatica* was probably in the Eurasian Near East, as a derivation from the same ancient fasciolid or a *F. gigantica*-close old form introduced with ruminants from Africa during a major sea level lowering in the early Miocene. The *F. hepatica* origin was likely the result of colonization and adaptation to a northern temperate-colder region, including two host capture phenomena to smaller lymnaeid species as *Galba* and to mid-sized ruminants (Mas-Coma et al., 2009a).

Fasciolids show a pronounced variability which is the consequence of thousands of years of animal movements and livestock exchange between areas, countries and continents during the livestock post-domestication period (Mas-Coma et al., 2009a). The result is the existence of local mixture puzzles whose origin interpretation is usually very difficult or highly speculative, in front of many accumulative waves of selfing and outcrossing flukes.

Genetic characteristics of fasciolids have been assessed by different techniques. In *F. hepatica*, the same isoenzymes were found regardless of the host species, but densities of some isoenzyme bands showed differences according to the host (Blair, 1993). Attempts by means of whole-body protein profiles and excretory/secretory products obtained with isoelectric focusing proved to be useless because fasciolids evidenced differences according to host species (Lee et al., 1992).

The aforementioned local mixture puzzles were evidenced when applying random amplified polymorphic DNA (RAPD), which showed that the majority of genetic diversity occurred within, rather than between animal hosts and was also greater within than

between populations, suggesting the influence of animal migrations and transportation (Semyenova et al., 2003). Similar results were later obtained by using a microsatellite approach (Beesley et al., 2017).

At present, fasciolid genotyping mainly relies on DNA sequencing of markers of the ribosomal DNA operon (rDNA) and the mitochondrial DNA genome (mtDNA). Sequencing of rDNA and mtDNA is useful to distinguish between *F. hepatica* and *F. gigantica* in overlap areas of Africa and Asia. In rDNA, the ITS-2 spacer is the best species marker (Mas-Coma and Bargues, 2009). In an analysis of “pure” *F. hepatica* from numerous countries and continents, only two 364-bp-long ITS-2 haplotypes and only one 432-bp-long ITS-1 were found. In “pure” *F. gigantica*, only one ITS-2 and one ITS-1 were found. The two species differ by five polymorphic sites at ITS-2 and other five at ITS-1 (Mas-Coma et al., 2009a). A wider comparison showed four ITS-2 haplotypes in *F. hepatica* and five in *F. gigantica*, whereas the ITS-1 was uniform in both species everywhere (Mas-Coma et al., 2009a).

In the mtDNA, the codifying genes *cox1* and *nad1* are the markers most used, mostly short fragments of them but in their complete length in a few studies. In *F. hepatica*, a total of 69 1533-bp-long *cox1* haplotypes and 23 510-aa-long COX1 protein haplotypes, and 51 903-bp-long *nad1* haplotypes and 15 300-aa-long NAD1 protein haplotypes were found in different continents (Mas-Coma et al., 2009a). In *F. gigantica*, a total of 11 1533-bp-long mtDNA *cox1* haplotypes and 5 510-aa-long COX1 protein haplotypes, and 15 903-bp-long mtDNA *nad1* haplotypes and 10 300-aa-long NAD1 protein haplotypes were found (Mas-Coma et al., 2009a).

Two single locus nuclear protein-coding genes, phosphoenolpyruvate carboxykinase (pepck) and DNA polymerase delta (pold) were proposed for fasciolid discrimination (Shoriki et al., 2016; Hayashi et al., 2018). Unfortunately, pepck revealed different heterozygosity and homozygosity levels with high length polymorphism and pepck multiplex PCR patterns could not differentiate between *Fasciola* species (Amor et al., 2020). The evaluation of the usefulness of pold is still pending.

The complete mitochondrial genomes of *F. hepatica* and *F. gigantica*, as well as that of an intermediate fasciolid form, have been already sequenced (Le et al., 2001; Liu et al., 2014). The *F. hepatica* genome has proved to be among the largest known pathogen genomes at 1.3 Gb. The substantial polymorphism levels found have tentatively been linked to the evolutionary potential for rapid adaptation to changes in host availability, climate change or to drug or vaccine interventions (Cwiklinski et al., 2015). Intriguingly, the *F. hepatica* genome from sheep of North America showed a markedly higher repeat content (55.29%) than the *F. hepatica* genome from cattle of United Kingdom (32.0%) (McNulty et al., 2017).

Biology

Life cycle

Both species follow a freshwater two host life cycle (Mas-Coma and Bargues, 1997). The adult stage lives inside the biliary canals and gallbladder, where it grows, matures and fecundates, by selfing or cross fertilization. Eggs are excreted outside with faeces via bile and intestinal lumen and those reaching freshwater will embryonate, giving rise to an inner miracidium.

The miracidium, of 130/28 µm, hatches under light stimulation and swims until contacting a freshwater snail of the family Lymnaeidae. The miracidium penetrates the snail and evolves into a 150–500-µm-long saccular sporocyst, which develops in the mantle, mantle collar or peri-esophageal area, and produces the subsequent stage of rediae. Rediae come out of the sporocyst and migrate mainly to the digestive gland. The first mother rediae in turn produce cercariogenous daughter rediae. Mature 250–750-µm long rediae are cylindrical, presenting a rudimentary digestive system (pharynx and a short caecum). Up to four redial generations have been found, although 2–3 generations are usual and follow the same developmental pattern in different lymnaeid species (Rondelaud and Barthe, 1986, 1987) according to a complex larval process (Rondelaud et al., 2009a).

Cercariae originate inside the rediae, escape through a birth pore, and are shed into water. The cercaria has a rounded spinose body of 28–320/250 µm, and a motile 700-µm-long tail. The prepatent period is dependent on temperature (15 °C: 56–86 days; 25 °C: 38 days). The shedding process in *F. hepatica* takes place between 9 °C and 26 °C. Cercariae swim for a short time (1 h) until contacting a solid support, mostly plants above or below the water line. They then lose their tails and quickly encyst, changing into metacercariae.

Metacercarial cysts are round, 200 µm in diameter, and infective within 24 h after encystment. Floating metacercarial cysts are also originated at the water surface line. Metacercarial cysts are resistant and viable for a long period, but are killed by excessive heat and dryness. Metacercariae infect the definitive host after ingestion, excyst in the small intestine within an hour, penetrate the intestine wall, and reach the abdominal cavity by about 2 h after ingestion. Most reach the liver within 6 days after excystment. In the liver they migrate for 5–6 weeks, and penetrate into bile ducts where they become sexually mature. It has been also speculated that juvenile flukes may (i) enter the blood stream and so reach various parts of the body, (ii) reach the liver by moving up the bile duct, or (iii) follow a very short intrahepatic migration (Chen and Mott, 1990; Moazeni and Ahmadi, 2016).

The prepatent period (from metacercariae ingestion to first egg appearance in faeces) varies according to the host: 35–42 days in mice; 55 days in guinea pigs; 63 days or 13–15 weeks in sheep infected with 200 or 2000 metacercariae, respectively; 56–61 days in cattle. In humans, the prepatent period is of at least 3–4 months (Mas-Coma and Bargues, 1997).

Intermediate hosts or transmission vectors

Freshwater Lymnaeidae snails are the vectors of the two *Fasciola* species. Each *Fasciola* species shows a different specificity regarding different lymnaeids. There are lymnaeid species which cannot transmit fasciolids, others transmit *F. hepatica*, others transmit

F. gigantica and a very few which have been reported to transmit both fasciolids. The lymnaeid species proved to be involved in the transmission of both *Fasciola* species in all continents have been reviewed in detail (Bargues et al., 2001).

Fasciola hepatica is mainly transmitted by small-sized *Galba/Fossaria* group species (Bargues et al., 2007, 2011a), including *Galba truncatula* as the most efficient vector (Bargues et al., 2017) and the only one in Europe, but also present in Africa, Asia and South America (Fig. 2A). The wide knowledge and literature on *G. truncatula* have been appropriately reviewed (Rondelaud et al., 2009b). Other vector species of this group include: *Lymnaea humilis*, *L. bulimoides* and *L. cubensis* in North America; *L. cubensis* in the Caribbean (Fig. 2C); *L. neotropica*, *L. cousini* and *L. viator* in South America; and *L. tomentosa* in Australia. The discovery of the nontransmitting species *L. schirazensis*, always confused with *G. truncatula* and other similar vector species throughout, highlighted specimen classification problems distorting fasciolid–snail specificity/susceptibility and fascioliasis geographical distribution data (Bargues et al., 2011a).

Species of the genus *Radix* transmit *F. gigantica*, mainly *R. natalensis* in Africa and varieties of *R. auricularia* (Fig. 2B) and *R. viridis* in Asia (Bargues et al., 2001; Ashrafi and Mas-Coma, 2014). *Pseudosuccinea* only includes the species *P. columella* which appears to be able to transmit both fasciolids (Bargues et al., 2011c) and has recently colonized all continents (Bargues et al., 2011c; Lounnas et al., 2017).

A few lymnaeid species among the stagnicoline group have proved their capacity to transmit *F. hepatica* under exceptional or local natural conditions in a few areas, such as *L. (Stagnicola) palustris*, *L. (S.) fuscus*, and *Omphiscola glabra* (Bargues et al., 2003).

The geographical distribution of the lymnaeid vectors species defines not only the distribution of fascioliasis, but may also explain the distribution of human infection within a country (Fig. 3A–D), as has been recently observed in Venezuela (Bargues et al., 2011b) and Chile (Artigas et al., 2011), and, within an endemic area, its seasonality or permanent transmission (Mas-Coma et al., 1999c; Bargues et al., 2020, 2021).

Fig. 2 Lymnaeid vector species transmitting fascioliasis: (A) *Galba truncatula* from Spain, the most efficient vector of *Fasciola hepatica*; (B) specimens of *Radix auricularia* transmitting *F. gigantica* in Guilan, Iran, showing shell variability; (C) specimens of *Lymnaea cubensis* from Cuba. Photographs S. Mas-Coma.

Fig. 3 Eco-epidemiology of main species of lymnaeid snail vectors of fascioliasis: (A) most small-sized lymnaeid vectors of the *Galba/Fossaria* group transmitting *Fasciola hepatica* show an evident amphibious trend, as shown by *Galba truncatula* on mud in Europe; (B) the *Fasciola gigantica* transmitting lymnaeid species *Radix viridis* is also a small-sized amphibious snail in South East Asia; (C) the *F. gigantica* transmitting *Radix auricularia* is a large-sized lymnaeid pronouncedly more aquatic in the Near East; (D) in the Nile Delta in Egypt, *Galba truncatula* and *Radix natalensis* coexist in the same irrigation canals surrounding vegetable cultivated fields and villages where inhabitants are co-infected by *F. hepatica*, *F. gigantica* and intermediate hybrid fasciolids. Photographs S. Mas-Coma.

Definitive host Spectrum and animal reservoirs

Adult fasciolids infect herbivorous mammals, mainly ruminants as sheep, goats, cattle and domestic buffaloes. Cattle and sheep are usually the most important animal reservoirs regarding human infection (Fig. 4A) (Mas-Coma et al., 2020a). Goats react to fasciolosis similarly to sheep, although their trend to more dry areas make them to be a secondary reservoir. Buffaloes are also of epidemiological importance in human endemic areas, mainly in Asia and Africa, where it is a preferential host for *F. gigantica* (Fig. 4B). Grazing domestic pigs may also be infected, but this host usually shows a higher natural resistance (Mas-Coma and Bargues, 1997).

Equids are alternate hosts which may play a role in the epidemiology of the disease and have been recently in the focus (Howell et al., 2020; Mas-Coma et al., 2020b). Horses appear to be more resistant to liver fluke infection than donkeys (Dorchies, 2010), with mules showing an intermediate susceptibility (Mera y Sierra et al., 2020).

Many other herbivorous domestic and wild animals may also be infected. Infection in Old and New World camelids has been repeatedly reported. Wild herbivorous mammals such as buffalo, deer, wild sheep, wild boar, various marsupials, rabbit and hare are also susceptible hosts. Many African wild animals have been also found naturally infected by *F. gigantica* (Losos, 1986). Additional to capybara and nutria, several rodent species have been found naturally infected by *F. hepatica* and others are usually used for experimental purposes.

Epidemiology

Geographical distribution

Livestock fascioliasis has been reported from almost all countries, except the most extreme northern latitudes. Fascioliasis is a worldwide veterinary problem. It is the vector-borne parasitic disease presenting the widest latitudinal, longitudinal and altitudinal distribution known at present (Mas-Coma et al., 2003, 2005). In the last three decades, it proved to be an important public health problem as well. The increasing human case and community reports throughout and results on pathogenicity and immunity studies

Fig. 4 Main domestic animal reservoirs of fascioliasis: (A) sheep and cattle grazing around small creek inhabited by amphibious *Galba truncatula* snails in a typical *Fasciola hepatica* transmission focus in the Southern Caucasus; (B) in Near East Asia, buffaloes tend to refresh inside deep freshwater collections inhabited by *Radix auricularia*, where they become infected by *Fasciola gigantica*. Photographs S. Mas-Coma.

were the reasons why it was decided to no longer consider fascioliasis a secondary human disease but an important one, not only in rural areas of developing countries (Mas-Coma et al., 1999a), but also concerning from individual patients to small epidemics in developed countries (Mas-Coma, 2020). It was therefore included as a food-borne trematode disease priority within the World Health Organization agenda (WHO, 2013).

Present estimations on human fascioliasis reach from 2.4 million up to 17 million people, or even higher depending from the hitherto unknown situations in Asia and Africa (Mas-Coma, 2004). A global analysis shows that the expected correlation between animal and human fascioliasis only appears at a basic level. High prevalences in humans do not seem to be necessarily related to high prevalences in livestock. Within a human endemic area, human infection appears irregularly distributed, with patchy transmission foci linked to lymnaeid-inhabited water collections (Fig. 5A and B) (Mas-Coma et al., 1999c).

Although human infection may occur in all animal endemic areas, the major health problems have been reported from Andean countries (Bolivia, Peru, Chile, Argentina), Central America (Mexico, Costa Rica), the Caribbean area (mainly Cuba but also Haiti), northern Africa (Egypt), the Near East (Iran and neighboring countries), southern Asia (Pakistan), and Southeast Asia (mainly Vietnam) (Mas-Coma et al., 2005, 2009a). The highest prevalences and intensities in humans have been reported in the Northern Altiplano in Bolivia and Peru (Esteban et al., 1999, 2002), the Cajamarca province in Peru (Gonzalez et al., 2011), and the region of the Nile Delta in Egypt (Esteban et al., 2003). Areas presenting lower human endemics and/or human reports concern: Venezuela, Ecuador, Brazil and Uruguay in the Americas; Ethiopia, Tanzania and South Africa in Africa; and India, Laos and southern China in Asia. Sporadic cases are being diagnosed throughout Europe, although mainly in western Europe (France, Portugal, Spain, Italy and Switzerland) (Mas-Coma, 2020). The impact of this disease in all kind of travelers has recently been reviewed (Ashrafi et al., 2014).

The different temperature thresholds of the two fasciolids underlie different preferences in seasonal, latitudinal and altitudinal distribution (Mas-Coma et al., 2009a). Thus, *F. hepatica* is mainly transmitted during the colder months, prefers temperate latitudes

Fig. 5 The anthropophilic behavior of given lymnaeid vector species assures fascioliasis transmission close to human dwellings and therefore increases human infection risk: (A) *Galba truncatula* transmission focus of *Fasciola hepatica* inside village in the Northern Bolivian Altiplano; (B) *Radix viridis* transmission focus of *Fasciola gigantica* in irrigated fields surrounding village in Vietnam. Photographs S. Mas-Coma.

and appears markedly confined to highlands in tropical and subtropical regions. Contrarily, *F. gigantica* is mainly transmitted during the warmer months, prefers warmer latitudes and appears markedly confined to lowlands in tropical and subtropical regions.

The two fasciolids overlap in several regions of Africa and Asia. Two new epidemiological terms were proposed for these areas (Mas-Coma et al., 2009a): (i) local overlap, where the two species are transmitted in neighboring foci or the same focus when the respective specific lymnaeid vectors share the same freshwater collection, and (ii) zonal overlap, where the two species are transmitted within the same area but *F. gigantica* foci are in the lowlands and *F. hepatica* foci in the nearby highlands (Fig. 6). Both overlaps furnish hybridization opportunities and consequent appearance of intermediate forms, as in the local overlap in the Nile Delta, Egypt (Periago et al., 2008), and the zonal overlap in Guilan, Iran, respectively (Ashrafi et al., 2015).

Human infection sources

A worldwide analysis has clarified all human fascioliasis infection sources, their diversity in the different areas and countries, the related incidence factors, and the methods for the study and analysis of these sources (Mas-Coma et al., 2018). The diversity of infection sources in different countries underlies the large epidemiological heterogeneity of human fascioliasis throughout (Mas-Coma et al., 2018):

- Ingestion of freshwater wild plants: main aspects to be considered are the plant markers of transmission foci, watercress, other freshwater wild plants, and wild plants sold in urban markets
- Ingestion of freshwater cultivated plants, mainly watercress

Fig. 6 Altitude is a crucial factor in the distribution of lymnaeid species of the *Galba/Fossaria* and *Radix* groups and in the temperature thresholds of development of the fasciolid species: *Fasciola gigantica* and *F. gigantica*-like forms predominate in the *Radix auricularia* inhabited lowlands, whereas *Fasciola hepatica* and *F. hepatica*-like forms predominate in the *Galba truncatula* inhabited highlands, in the zonal overlap in Guilan, Iran. Animal movements and transhumance underlie the exchange of livestock between lowlands and highlands. Schema S. Mas-Coma.

- Ingestion of terrestrial cultivated plants needing frequent irrigation
- Ingestion of terrestrial wild plants: collected in dry habitats but which were submerged in water a few weeks or months before
- Ingestion of traditional local dishes made with contaminated sylvatic plants
- Ingestion of raw liver infected with migrating metacercariae which may keep the capacity to restart migration
- Drinking of contaminated water
- Drinking of beverages and juices made from local plants
- Ingestion of dishes and soups made with contaminated water
- Washing of vegetables, fruits, tubercles, kitchen utensils or other objects with contaminated water.

Among the incidence factors, disease transmission seasonality, the infectivity of metacercariae under field conditions, as well as several community, familial and social factors in infection risk appear in the forefront. The methods to assess human infection sources include: (i) detection of metacercariae attached to plants or floating in freshwater; (ii) anamnesis in individual patients, and (iii) questionnaire surveys in endemic areas (Mas-Coma et al., 2018).

Metacercarial infectivity is dependent upon storage time, being lower when metacercariae are older, and do not differ between isolates from different reservoir species (Valero and Mas-Coma, 2000).

Transmission patterns and epidemiological situations

Fascioliasis presents a very wide spectrum of transmission and epidemiological patterns in human hypo- to hyperendemic areas. A classification of transmission patterns has been proposed (Mas-Coma, 2005) and is progressively updated to offer a baseline for future research (Mas-Coma et al., 2009a; Valero et al., 2012b; Bargaes et al., 2016).

A useful epidemiological classification of human infection situations has been proposed (Mas-Coma et al., 1999a, 2009a), including:

- (1) Autochthonous, isolated, nonconstant cases;
- (2) Imported cases;
- (3) Hypoendemic (prevalence less than 1%);
- (4) Mesoendemic or holoendemic (prevalence between 1% and 10%);
- (5) Hyperendemic (prevalence higher than 10%);
- (6) Epidemics in nonhuman endemic but animal endemic areas (family or small group reports);
- (7) Epidemics in human endemic areas (higher number of subjects may be concerned).

In the human hyperendemic areas, 5–15-year-old school children are the group most affected (Fig. 7A and B). However, in other human endemic areas, infection peaks at an adult age (usually between 30 and 40 years old). Fascioliasis appears to affect more females than males, this preference for females being detected in prevalences or intensities according to areas. However, infection in humans may occur earlier than previously expected, from early postnatally infected lactants to pre-school age and, in such small children, males instead of females are the most infected (De et al., 2020).

Fig. 7 Children are the age group most infected by fascioliasis in human hyperendemic rural areas of developing countries: (A) 5–15-year-old schoolchildren have a high risk of fascioliasis infection along the ways from home to school and back in the Northern Bolivian Altiplano; (B) the closeness of livestock grazing, activities of children, and cloth and utensil washing by women underlie their high infection rates, as in the Mantaro valley in Peru. Photographs S. Mas-Coma.

Influences of climate change and global change

Climatic factors are decisive in fascioliasis transmission. Seasonal variation of rainfall and temperature gives rise to different fascioliasis seasonality. In Europe, the transmission is typically bi-seasonal, due to the lymnaeid vector activity in spring and autumn. In the Bolivian Altiplano, the transmission takes place along the year, lymnaeids inhabiting permanent water bodies instead of temporary ones due to the high altitude evapotranspiration (Mas-Coma et al., 1999c; Bargues et al., 2021). In other areas, the transmission is mono-seasonal, due to only a season with surface water availability.

Global warming is a crucial factor. In the Bolivian Altiplano, at 3820–4100 m a.s.l., recent increased temperatures have allowed the lymnaeid vector to colonize zones of higher altitudes outside the previously established borders of the endemic area, with the consequent spread of the human infection risk area (Bargues et al., 2020).

Climate change overlaps anthropogenic and environmental modifications which give rise to suitable new environments for the lymnaeid vectors and influence transmission seasonality (Mas-Coma et al., 2009b). Thus, artificial field irrigation is sufficient by its own to allow for fascioliasis transmission in Cambodia (Tum et al., 2007). In Pakistan, transmission follows bi-seasonality with a peak related to rainfall and another related to man-made irrigation (Afshan et al., 2014b). Establishing fascioliasis emergence causality in such an influencing factor overlap may sometimes be difficult.

Three types of approaches are useful for the study of climate and environment influences on fascioliasis, including the assessment from geographical distribution and seasonality up to human and animal infection risk and forecasting methods, namely mathematical modelling based on climate factors, remote sensing (RS) based on images and information furnished mainly by space satellites, and geographic information systems (GIS) based on computer mapping by geo-positioning of different abiotic and biotic

factors and characteristics. These methods allow for developments from low to very high resolution adapted to endemic areas of different characteristics (Malone et al., 2019).

The disease

Phases, pathology, symptomatology and impact

Fascioliasis is a highly pathogenic disease in both humans and animals. Fascioliasis has a large economic and trade impact on husbandry and import/export of livestock, globally (Mehmood et al., 2017) and in different countries (Schweizer et al., 2005; Mazeri et al., 2017), including countries where human fascioliasis is a wide health problem (Espinoza et al., 2010). An estimation of total world economic losses in only cattle and buffalo reached US\$ 3.2 billion (Copeman and Copland, 2008).

In humans, fascioliasis causes community underdevelopment in rural areas of low income countries. There is much clinical variability related to (i) the burden (flake number infecting the patient), (ii) disease phase or period, and (iii) host individual susceptibility. Four periods may be distinguished (Chen and Mott, 1990; Mas-Coma and Bargues, 1997; Mas-Coma et al., 1999b, 2000, 2014a):

- Incubation phase: From the ingestion of metacercariae to symptom onset.
- Acute, invasive or migratory phase: It corresponds to the fluke migration up to the bile ducts. The symptomatology is due mainly to mechanical destruction of liver tissue and abdominal peritoneum by the migrating larvae causing localized or generalized toxic and allergic reactions lasting 2–4 months. This phase includes fever, abdominal pain usually in the right hypochondrium or below the xyphoid, gastrointestinal disturbances such as loss of appetite, abdominal flatulence, nausea and diarrhea, respiratory symptoms such as cough, dyspnea, hemoptysis, urticaria and chest pain.
- Latent phase: From arrival to biliary canal until starting of oviposition. It can last from days to years and show eosinophilia, gastrointestinal complaints or one or more acute symptom relapses.
- Chronic, biliary or obstructive phase: This period may develop after months to years of infection. Adult flukes in the bile ducts cause inflammation, hyperplasia of the epithelium, and thickening and dilatation of duct and gall bladder walls. Cholangitis and cholecystitis, combined with the large body of the flukes, may be sufficient to cause obstruction. This period includes biliary colic, epigastric pain, fatty food intolerance, nausea, jaundice, pruritus, right upper-quadrant abdominal tenderness and Murphy's sign, among others. Lithiasis of the bile duct or the gall bladder is frequent, whereas cirrhosis does not appear to be so. The bile duct and the gall bladder may contain blood mixed with bile (haemobilia), blood clots and fibrinous plugs.

The comparison of the development of *F. hepatica* and *F. gigantica*, followed for the first time in the same animal host, demonstrated a higher pathogenicity by *F. gigantica*. This result was opposite to previous studies indicating a higher *F. hepatica* pathogenicity and which in fact was only reflecting the faster development of *F. hepatica* observed in short-term experiments (Valero et al., 2016).

The fasciolid life span in humans is between 9 and 13.5 years, which suggests acute lesions by re-infections to occur superimposed on both latent and obstructive phases in human endemic areas (Chen and Mott, 1990; Valero et al., 2017). This very long life span underlies complications and sequelae in long-term chronicity (Mera y Sierra et al., 2011), even after successful treatment (Rondelaud et al., 2006).

Before the 1990s, clinical studies had mainly focused on the acute phase because human infection was mainly detected in industrialized countries in which patients attended health centers usually after symptom onset. The scenario changed in recent years because in rural areas of low income countries quick health care is not always available and most children infections are diagnosed in the chronic phase in surveys. Therefore, increasing studies are now focusing on the chronic phase, whether in animal models or infected patients. The long-term impact of chronicity has shown to lead to gallstone appearance, bacteriobilia (Valero et al., 2003, 2006), long-term liver function alterations (Valero et al., 2016) and also cirrhosis (Marcos et al., 2009). Worth mentioning results demonstrated that a high risk of anemia is to be expected in subjects with a heavy fluke burden, which is frequent in children in human hyperendemic areas (Valero et al., 2008).

During the intraorganic migration, immature flukes may deviate, enter other organs and cause ectopic fascioliasis. The most frequent ectopic lesions are those of the gastrointestinal tract. Other ectopic lesions are in: abdominal wall, pancreas, spleen, subcutaneous tissue, heart, blood vessels, the lung and pleural cavity, brain, skeletal muscle, appendix and epididymis. Such ectopic flukes almost never achieve maturity. The usual pathological effects of ectopic lesions are due to the migratory tracks causing tissue damage with inflammation and fibrosis (Mas-Coma et al., 2014a).

Neurofascioliasis (= intracranial infection by *Fasciola*) and ophthalmofascioliasis (=ocular affection by migrating flukes) may be rare, although not sporadic as previously believed. However, manifestations including many neurological symptoms, signs and syndromes, together with meningeal, psychiatric or neuropsychic manifestations, and ocular disorders caused at distance by flukes infecting the liver may be frequent but underestimated due to misdiagnosis (Mas-Coma et al., 2014a). Impressive clinical pictures include from hemiplegia and paraplegia to disturbances and difficulties of walking capacity, speech disorders, convulsions, epilepsy and coma, amnesia, or visual hallucinations and permanent blindness, among other manifestations. Moreover, there is a clinical complexity of puzzling polymorphisms, a disconcerting multifocality of the manifestations, and their changes along the evolution of the disease in a same patient, as well as differences between the clinical pictures shown by different patients. Additionally, these studies emphasized post-treatment sequelae and mortality in neurological patients (Mas-Coma et al., 2014a).

Numerous plasminogen-binding proteins enhancing plasmin generation, most of which cathepsins of well-known immunomodulating effects, were identified in the *F. hepatica* excretome/secretome (Gonzalez-Miguel et al., 2019). This was suggested to underlie blood-brain barrier leakage whether by many simultaneously migrating, small-sized juvenile flukes in the acute phase, or by breakage of encapsulating formations triggered by single worm in the chronic phase. Blood brain barrier leakages may subsequently occur due to a fibrinolytic-contact system-dependent mechanism involving plasmin-dependent generation of the proinflammatory peptide bradykinin, after different plasminogen-binding protein agglomeration waves, and in that way explain the complexity, heterogeneity and timely variations of neurological disorders caused in humans by fasciolids located in the liver (Gonzalez-Miguel et al., 2019).

Immunity

Fasciolids develop immune-modulation mechanisms which underlie their wide mammal host spectrum specificity.

In cattle the disease is self-limiting, most of the flukes are eliminated within 9–12 months, the duration of egg production is short and high egg output lasts for only a few weeks, and resistance is acquired during primary infection (Mas-Coma et al., 2020a). Nucleotide polymorphisms in given regions of the bovine genome have been recently found in cattle presenting resistance to *F. hepatica* (Twomey et al., 2019). In cattle, a mixed response with high levels of IL-10, TGF- β , IL-4 and IFN- γ occurs during the acute phase. Subsequently, Th2/Treg immune responses become progressively dominant. In the chronic phase, these Treg cells produce cytokines which cause inflammatory Th1/Th2 cytokine inhibition (Flynn et al., 2007). In sheep, the immune response is similar, including a mixed Th1/Th2 cytokine profile in the acute phase which later leads to increased Th2 cytokines instead of Th1 ones (Alvarez Rojas et al., 2015), with IL-10 dominating at spleen level and IL-5 in hepatic lymph nodes (Hacariz et al., 2009a; Pleasance et al., 2011a).

In sheep, there is no evidence of acquired immunity against *F. hepatica*, although resistance to *F. gigantica* is reported in Indonesian Thin Tail sheep (Pleasance et al., 2011b). The only breed in which similar susceptibility to both fasciolids has been reported is Guirra sheep (Valero et al., 2016). In sheep, egg output is relatively high (4000–50,000 eggs per fluke/day and 8800–25,100 eggs per host in weeks 13–19 post-infection). Thus, sheep may play a more important role in pasture contamination and consequently in disease transmission (Mas-Coma et al., 2020a).

In ruminants as in rodent model hosts, a potent regulatory/Th2-type response has been described to underlie Th1 immune suppression (Brady et al., 1999; O'Neill et al., 2000; Flynn and Mulcahy, 2008; Hacariz et al., 2009b; Pleasance et al., 2011b). The immune response in advanced chronic fascioliasis in the Wistar rat, in which experimental results proved to be reasonably extrapolable to humans, showed serum cytokine quantification to be at basal levels, with IgG1 as the predominant immunoglobulin isotype. There were no significant differences in T cell (CD3+, CD4+, and CD8a+), B cell (CD45R+), and macrophage (CD11b+) populations in the spleen between infected and noninfected rats, and the proliferation of splenic mononuclear cells in response to T and B mitogens was strongly inhibited. The predominant Th2 response in the early chronic infection subsequently decreased giving rise to a persistent immune suppression in the advanced chronic infection (Girones et al., 2007). It should be considered that, in human hyperendemic areas, children are always or almost always diagnosed in the advanced chronic phase of fascioliasis, and reinfection is frequent.

In the chronic phase characterized by a mixed Th2/Treg expression together with IFN- γ and associated Th17, reinfection is able to activate a mixed Th1/Th2/Th17/Treg immune response. However, T and B proliferation to mitogens is strongly suppressed in the advanced chronic phase independently of reinfection. Results suggested that suppression is mediated by different mechanisms, i.e. due to the parasite in primo-infected rats and rats reinfected at 8 weeks, and to the induction of suppressive cells such as Treg in rats reinfected at 12 weeks. In reinfection, two phenotypic patterns were detected: (i) one correlating with severe anemia which includes only increased splenic IFN- γ expression levels but no Treg expression; (ii) another correlating with a less severe anemia which includes increased splenic IFN- γ and Treg expression levels (Valero et al., 2017). In rats reinfected at 8 weeks and at 12 weeks, transiently higher averages of epg and epg/worm were detected in the weeks following reinfection. Such egg increases correlated with transient increases of IgG1 levels, systemic IL10 and thymic IFN- γ , and IL10 expression levels. This suggests that egg production depends on the Th1 and Treg phenotype, and means that fluke burden estimation by epg may likely be an overestimation in recent reinfection cases (Valero et al., 2020).

Fasciolids interact with several cells involved in innate immunity. CD11c⁺ dendritic cells have been seen to increase, with lower expression of co-stimulatory markers, MHC class II, increased expression of CCR5, and are hyporesponsive to TLR activation (Dalton et al., 2013). These dendritic cells increase intracellular IL-10, and the secretion of antigen specific IL-17 and IFN- γ becomes suppressed (Walsh et al., 2009). Regulatory/M2 phenotype macrophages are induced early in infection (Donnelly et al., 2008; Flynn et al., 2007). These macrophages are TLR ligand hyporesponsive and therefore suggest a low capacity to promote the differentiation of host Th1 immunity, and have proved to promote the polarization of Th2 cells (Donnelly et al., 2008). A mast cell number increase occurs at the infection site and gut mucosa (van Milligen et al., 1998; Vukman et al., 2013), which is thought to be involved in the reparation of the tissue damage caused by migratory fasciolid juveniles (Robinson et al., 2010). T cells are induced to enter an anergic state characterized by a decreased cytokine responses and reduced proliferative activity (Aldridge and O'Neill, 2016) and may explain why these cells become hyporesponsive to antigen stimulation in the chronic phase.

In coinfection with other pathogens, the synergistic capacity of fasciolids is well known, immune responses to pathogen antigens being markedly suppressed and concomitant infection being exacerbated. Protozoan and helminthic species, multi-parasitisms, and associations between infection by fasciolids and other parasites, are similar in inhabitants of the different human hyperendemic

areas (Esteban et al., 1997a,b, 2002, 2003; Gonzalez et al., 2011). These synergistic associations of fascioliasis with other pathogens may induce higher morbidity and even mortality rates (Mas-Coma, 2004).

Diagnosis

Alterations in biochemical markers, mainly liver function tests, and markers such as eosinophilia, are helpful initial indicators of an helminth infecting the liver. Radiology, radioisotope scanning, ultrasound, computed tomography and magnetic resonance may be additionally helpful (see reviews in Esteban et al., 1998 and Hillyer, 1999). Fluke adults and eggs may be found by invasive techniques, such as surgical interventions (laparotomy, cholecystectomy, sphincterotomy) or histological examination of liver and/or other organ biopsy materials (Mas-Coma et al., 1999b).

For the differential diagnosis of *F. hepatica* and *F. gigantica*, clinical, pathological, or immunological methods are useless. This is a problem in overlapping areas because of the different pathological, transmission and epidemiological characteristics of the two fasciolids, as well as due to intermediate forms in which egg measurements may overlap. Despite the recent development of many molecular tests, DNA marker sequencing still remains the best method for both pure fasciolid species haplotyping and detection of hybridization in intermediate forms (Mas-Coma et al., 2009a).

Stool and blood techniques, the main diagnostic tools, have been improved in the last two decades. Present availabilities for human diagnosis have recently been reviewed exhaustively, focusing on advantages and weaknesses, sample management, egg differentiation, qualitative and quantitative diagnosis, antibody and antigen detection, post-treatment monitoring, and post-control surveillance (Mas-Coma et al., 2014b). Main conclusions referred to the pronounced difficulties of diagnosing fascioliasis given the different infection phases and parasite migration capacities, clinical heterogeneity, immunological complexity, different epidemiological situations and transmission patterns, and the lack of a diagnostic technique covering all needs and situations (Mas-Coma et al., 2014b).

Direct and indirect techniques for human diagnosis

Fasciolid egg finding in human stool samples, but also endoscopic aspirates of duodenal or bile contents, is the most usual diagnostic strategy to qualitatively and quantitatively assess infection, despite egg absence during the acute period and sensitivity problems in chronic cases of very low intensity. Coprological techniques from a simple direct smear to different concentration methods may be used. Egg concentration has been achieved by flotation and sedimentation techniques, the latter being more accurate and sensitive (Esteban et al., 1998; Mas-Coma et al., 1999b, 2014b).

Quantitative coprological analyses are important in epidemiological surveys, post-treatment monitoring, and to decide the appropriate treatment dose to avoid colic risk in patients presenting with high burdens (WHO, 2007; Valero et al., 2012a). The Kato-Katz technique appears to be appropriate, because of its simplicity, very low cost, and reproducibility (Mas-Coma et al., 1999b). Its low sensitivity may be solved by repeated application.

Immunological techniques include mainly serological tests and a few whole blood tests based on immunological reactions. Numerous serological, intradermal and stool antigen detection tests have been developed. Immunological techniques present several advantages which solve problems posed by the parasitological diagnosis, such as: (i) its uselessness in the acute period because coprological examination is positive only after 3–4 months post-infection, (ii) intermittent egg output dynamics, (iii) very low or even absence of egg shedding in cases of only one or a few fluke adults and old, chronic infections, (iv) ectopic infections, (v) “false” fascioliasis related to eggs in transit after ingestion of infected liver from domestic animals, or (vi) flukes unable to attain maturity in human subjects in nonhuman endemic areas (Mas-Coma et al., 2014b).

However, immunological techniques are not able to differentiate between *F. hepatica* and *F. gigantica*. The negativization delay of serological antibody-detecting techniques also pose problems in post-treatment monitoring. Moreover, they are useless to assess fluke burden and consequently are not helpful in establishing the appropriate treatment dose, above all in human hyperendemic areas where high intensities are frequent. Additionally, several immunological techniques offer other types of problems related mainly to sensitivity and specificity (Valero et al., 2012c).

Cysteine proteinases offer highly sensitive and specific markers for human fascioliasis serodiagnosis (Fig. 8) (Mas-Coma et al., 2014b). *Fasciola hepatica* recombinant cysteine proteinases produced in yeast (O'Neill et al., 1999) or in *Escherichia coli* (Carnevale et al., 2001) have been used as antigens in ELISA methods.

The MM3 coproantigen-detection test allows for high sensitivity and specificity, fast large mass screening capacity, detection in the chronic period, early detection of treatment failure or reinfection in post-treated subjects, and usefulness for surveillance programs (Valero et al., 2012a). The use of a new preservative/diluent CoproGuard™, developed for preservation of *Fasciola* coproantigens, proved to enhance coproantigen extraction and antigenicity throughout the complete observation period (Ubeira et al., 2009). However, this technique falls short when evaluating the fluke burden on its own, and failed in a few cases of children shedding eggs (Valero et al., 2012a). This MM3 coproantigen-detection test has therefore recently been improved to increase its sensitivity (Martínez-Sernández et al., 2016).

A new lateral flow test (SeroFluke) for human diagnosis appears to be a useful step forward (Martínez-Sernández et al., 2011). In comparison with an ELISA test (MM3-SERO), SeroFluke showed maximal specificity and sensitivity and the advantage of being applicable to both serum or whole blood samples.

Fig. 8 Fascioliasis seropositive samples from hospital patients in Quy Nhon, central Vietnam. Photographs S. Mas-Coma.

In the exhaustive review of human fascioliasis diagnosis, it was concluded that there is at present no diagnostic technique covering all needs and situations and therefore an evident advisability for a combined use of different techniques, at least including a stool technique and a blood technique (Mas-Coma et al., 2014b).

Diagnosis in livestock

In livestock, diagnosis of animal infection, evaluation of drug efficacy and of drug resistance should be distinguished. A number of tests are available, including a few tests allowing for burden estimation by quantification by fecal egg counts, serological and coprological methods, egg hatch assays, molecular techniques, and even histological methods (Charlier et al., 2008; Fairweather et al., 2020). Specific reviews on diagnosis in sheep (Rojo-Vazquez et al., 2012) and cattle (Charlier et al., 2008) have recently been made.

A bulk tank milk ELISA has been used to survey for fluke prevalence in dairy herds across regions and across seasons (Byrne et al., 2018).

The coproantigen detection test is suitable for the diagnosis in sheep, cattle and deer, but not horses (Palmer et al., 2014).

Egg formation, production, development and viability are crucial in fascioliasis transmission and sensitive to drug action. A number of protocols or egg hatch tests have been developed to study drug action impact on the development and hatching of fasciolid eggs, but there is no standardized method (Fairweather et al., 2020).

Molecular methods, mainly targeting the mtDNA *cox1* gene or the nuclear rDNA ITS-2, have been proposed for the detection of *F. hepatica* in fecal samples from sheep and cattle, including the polymerase chain reaction (PCR), loop-mediated isothermal amplification (LAMP), and recombinase polymerase amplification (RPA). Such methods are however not easy to be applied in remote rural areas, mainly in front of simple and less expensive coprological egg detection.

Treatment

From the first half of last century, many drugs have been used to treat human fascioliasis. Emetine derivatives were used widely. Dehydroemetine, at a dose of 1 mg/kg daily for 10–14 days, was even considered the therapy of choice a few decades ago (Esteban et al., 1998).

Bithionol was proposed as the drug of choice during the last three decades of last century. It was applied at a dose of 30–50 mg/kg daily, divided into three oral doses on alternate days for 20–30 days. In cases of fascioliasis resistant to emetine and praziquantel (PZQ) treatment, bithionol achieved cure in dosages of 50 mg/kg daily for 10 alternate days or 40 mg/kg daily for 14–15 alternate days. Occasionally, the patients required a second course to obtain a complete cure (Chen and Mott, 1990; Esteban et al., 1998).

PZQ was widely applied during the 1980s and 1990s, because it is the drug of choice for human trematodiasis. However, controversial results were found in fascioliasis patients, including treatment failures even at high doses. Today, it is generally accepted that *Fasciola* may be the only trematode genus that has practically no response to PZQ (Esteban et al., 1998).

Among imidazole derivatives, cure rates of up to around 70% have been reported with albendazole, but triclabendazole (Egaten®) has become the drug of choice for human fascioliasis (Savioli et al., 1999; Gandhi et al., 2019). This drug is better adsorbed if administered after meals. The recommended regime is two doses of 10 mg/kg separated 12 or 24 h, with cure rates of around 80% after a first dose and higher than 95% after two doses. In patients shedding more than 400 eggs, absence of secondary

effects should be verified before second dose administration (WHO, 2007; Valero et al., 2012a). The need for a third dose has been reported sporadically.

The risk of triclabendazole resistance cannot be overlooked considering the veterinary use of triclabendazole (Fasinex®) for livestock treatment since long ago, the tradition of human self-treatments with Fasinex® owing to the very general availability of this drug, and the appearance of triclabendazole resistance in animals in different countries. So far, triclabendazole resistance only concerned a few patients infected in areas where resistance in animals was previously detected. Additionally, our understanding of the triclabendazole resistance mechanism remains far from complete, so that there is even a knowledge gap regarding its spreading capacity. A multigenic resistance origin has been suggested to underlie this resistance. Strategies to minimize the development of resistance include the use of synergistic drug combinations (Fairweather et al., 2020).

Nitazoxanide, a drug of broad parasitological spectrum, may be considered an alternative to triclabendazole, at least for chronic and low burden infections, in countries where Egaten® is still not registered but nitazoxanide is since several years (Zumaquero-Rios et al., 2013). Nitazoxanide demonstrated its efficacy in trials in Egypt and Peru. Its long 7-day treatment course is nevertheless a problem. However, its usefulness for human cases not responding to triclabendazole may be of additional value. Differences in fasciolid susceptibility to nitazoxanide may exist depending on geographical strains. Thus, no response to nitazoxanide treatment was reported in Cuba, and a triclabendazole-resistant *F. hepatica* infected patient not responding to nitazoxanide was reported in the Netherlands. Nitazoxanide proved, however, to be effective for the treatment of children in a human endemic area of Mexico where intensities are low (Zumaquero et al., 2013).

A number of existing flukicides for veterinary use are active against triclabendazole-resistant fasciolids, including albendazole, clorsulon, closantel, nitroxynil and oxiclozanide, although these alternatives do not act against migrating juveniles. Combinations of flukicides, anthelmintics and other drugs may be also useful (Vercruysse and Claerebout, 2001; Fairweather et al., 2020).

Prevention and control

Animal fascioliasis control efficiency depends on the correct and integrated application of: (i) reduction of parasite load of animal hosts and pasture contamination by regular strategic drug use (preventive treatment in appropriate year periods according to different regions); (ii) reduction of snail number by physical, chemical and biological means; (iii) reduction of infection risk through correct farm management practices (rotational system through fluke-infected and fluke-free paddocks, combined with effective treatment) (Fig. 9A and B) (Mas-Coma and Bargues, 1997; Fairweather et al., 2020).

Highly specific environmental DNA (eDNA) assays have been developed for the detection of *F. hepatica* and lymnaeid vectors in freshwater habitats (Jones et al., 2018; Rathinasamy et al., 2018). Such assays may be useful in farms, but their usefulness in open endemic areas pose many question marks, mainly where the lymnaeid vectors show a marked amphibious behavior.

Human infection was always related to animal endemics, so that prevention measures were traditionally the same to be applied at the levels of domestic animals, snails and field (Roberts and Suhardono, 1996; Torgerson and Claxton, 1999; Spithill et al., 1999). However, recent studies on human endemic areas have shown that epidemiological patterns of animal fascioliasis not always explain human infection characteristics.

The prevention of human infection may be achieved by strict control of the human infection sources in each place, mainly with regard to watercress and other metacercariae-carrying plants for human consumption (Mas-Coma et al., 2018). The possibility of human infection in urban areas should also be considered. Thanks to transport of vegetables (both aquatic and terrestrial) from rural zones to cities, plants carrying metacercariae can be sold in noncontrolled city markets (Fig. 10) (Mas-Coma et al., 2018). Additionally, commercial growing of watercress should be carried out under completely controlled conditions.

Education should always be included within general control measures in human endemic areas. The community should be appropriately informed about the disease, its transmission and danger, with emphasis on the human infection sources. The construction and utilization of the so-called “washing units,” in which water was appropriately filtered, gave rise to a marked decrease of human infection in an Egyptian locality (Mas-Coma, 2004; Mas-Coma et al., 2018).

In recent years, the availability of triclabendazole prompted WHO to launch a worldwide initiative against human fascioliasis (WHO, 2007, 2008). This initiative includes action in human endemic areas presenting different epidemiological situations and transmission patterns (Mas-Coma, 2005; Mas-Coma et al., 2009a). Pilot schemes were designed for the best control strategies according to local characteristics in Vietnam and Egypt. In Bolivia and Peru, pilot interventions demonstrated side effect absence in triclabendazole treatments of schoolchildren (Villegas et al., 2012), which subsequently allowed for preventive chemotherapy by annual mono-dose mass treatment campaigns. Many other countries are nowadays receiving yearly triclabendazole donations through WHO for the treatment of their patients.

In the Bolivian Altiplano, inter-annual treatment campaign monitorings detected infection and reinfection of children due to a high infection risk linked to the endemic maintained by livestock. A wide One Health action has therefore been launched to complement preventive chemotherapy, including control activities on: (i) environment and climate (Bargues et al., 2021), (ii) snail vector (Bargues et al., 2020), (iii) animal reservoirs (Mas-Coma et al., 2020a,b), (iv) human infection, and (v) social, tradition, diet, behavior and education factors (Mas-Coma et al., 2018). The ulterior purpose of this One Health action is to provide a guideline protocol applicable to other human endemic areas.

Introduction

Free living amoebae (FLA) are aerobic, mitochondriate, eukaryotic protists that are ubiquitous in nature and potentially infectious to humans (Schuster and Visvesvara, 2004; Visvesvara et al., 2007). The FLA are amphizoic in nature being able to reside as parasites within the host tissue (Page, 1988). They are commonly found in natural environment including air, water and soil (Edagawa et al., 2009; Huang and Hsu, 2010). They have also been isolated from drinking water, swimming pools, sewage, surgical instruments, dialysis units, eyewash solutions and contact lenses (Siddiqui and Khan, 2012a). Four genera of FLA including *Acanthamoeba*, *Naegleria*, *Balamuthia* and *Sappinia* are known to be pathogenic to humans (Schuster and Visvesvara, 2004; Visvesvara et al., 2007). These parasites have the potential to cause opportunistic infections among humans. The *Acanthamoeba* spp. is the causative agent of granulomatous amebic encephalitis (GAE) primarily among immunocompromised patients and *Acanthamoeba* keratitis (AK) among immunocompetent individuals (Alizadeh et al., 2014; Siddiqui and Khan, 2012a). *N. fowleri* causes primary amebic encephalitis (PAM) among healthy children and young adults (Cope and Ali, 2016). *Balamuthia mandrillaris* often causes fatal GAE and skin lesions among immunocompetent as well as immunocompromised patients (Matin et al., 2008; Bravo and Seas, 2012a,b). *Sappinia diploidea* has been reported in brain infection of a healthy man (Gelman et al., 2001).

Historical perspective

Amoebae are among the earliest eukaryotes that gained attention due to their role in causing fatal infections among humans. *Acanthamoeba* was discovered as a contaminant of yeast culture, *Cryptococcus parvulus* in Castellani (1930). In 1958, C. G. Culbertson demonstrated the concept that *Acanthamoeba* can cause disease among humans (Culbertson et al., 1958). While growing

poliomyelitis virus in monkey kidney cell cultures, Culbertson and his colleagues observed clear plaques in the control cell cultures. They inoculated experimental animals with the culture supernatant. They observed that the animals died with symptoms of meningoencephalitis. Culbertson isolated *Acanthamoeba* Lilly A-1 strain from the brains of dead animals. They later named this isolate as *Acanthamoeba culbertsoni*. Later, *Acanthamoeba* was described as the causative agent of GAE and keratitis infections in 1960s and 1970s, respectively (Castellani, 1930). In 1899, Schardinger discovered *Naegleria* and named it as "*Amoeba gruberi*." In 1912, Alexeieff renamed the genus as *Naegleria*. In later years, Rodney F. Carter and Malcolm Fowler reported first human case of PAM due to *N. fowleri* (De Jonckheere, 2002; Carter, 1972; Fowler and Carter, 1965). After that another amoeba *Balamuthia mandrillaris* was added to the list of free living amoebas. In the year 1986, free living amoeba *B. mandrillaris* was discovered from the brain tissue of a pregnant mandrill baboon (*Papio sphinx*) that died due to meningoencephalitis (Visvesvara et al., 1990, 1993). *Sappinia diploidea* is another free living amoeba that was identified as the causative agent of GAE in Gelman et al. (2001).

Taxonomic classification

The classical taxonomic classification divided Protozoa into four groups namely, Sarcodina (amoeba), Mastigophora (flagellates), Sporozoa (parasitic protozoa) and Infusoria (ciliates) (Visvesvara et al., 2007). However, later a new taxonomic classification based on the morphologic, biochemical and molecular approaches was put forth by the International Society of Protozoologists (Adl et al., 2005). As per this new proposal, the eukaryotes were placed under six clusters or "Super Groups," namely Amoebozoa, Opisthokonta, Rhizaria, Archaeplastida, Chromalveolata and Excavata. The four FLA were classified under two Super Groups, Amoebozoa and Excavata. *Acanthamoeba* and *Balamuthia* were classified under Super Group Amoebozoa: Acanthamoebidae. *N. fowleri* was classified under Super Group Excavata: Heterolobosia: Vahlkampfiidae. *Sappinia* was classified under Super Group Amoebozoa: Flabellinea: Thecamoebidae (Adl et al., 2005).

Acanthamoeba

Morphology

Acanthamoeba exists in two distinct morphological forms, viz., active trophozoites and dormant cysts. Trophozoites are actively feeding, dividing forms and their size ranges between 15 and 50 µm. They are uninucleate with a large, centrally placed nucleolus. The cytoplasm contains food vacuole, a contractile vacuole, mitochondria and ribosomes. They possess fine, tapering, surface structures called acanthopodia that are responsible for amoeboid movement (Khan, 2006). In the presence of unfavorable environmental conditions including food scarcity, desiccation or other environmental stresses amoeba transforms into a cyst i.e., encystation occurs (Khan and Tareen, 2003; Mazur et al., 1995). Cysts are double walled structures that can range from 10 to 25 µm. The outer cyst wall i.e., ectocyst is majorly made up of protein and lipid and gives wrinkled appearance. The inner cyst wall i.e., endocyst mostly contains cellulose that makes it periodic-acid Schiff positive and have smooth appearance (Visvesvara et al., 2007). Endocyst can be star, polygonal, oval or spherical in shape. Pores covered by opercula are present at the junction of ectocyst and endocyst. Cysts are also uninucleate and have a centrally placed nucleolus. Cysts are resistant to drying out, ultraviolet radiation, variable osmotic pressure, changes in humidity and can also survive at low temperatures (Khan, 2006). Upon favorable growth conditions, amoebae leave the cyst by dislodging the operculum and return to trophozoite form Fig. 1.

Genotypes of *Acanthamoeba* species

Earlier, *Acanthamoeba* spp. was identified based on their morphological characteristics such as shape and size of ecto- and endocyst walls as well as temperature required for their growth. But now-a-days, identification is primarily based on the use of molecular techniques (Khan, 2006). Till date, about 22 genotypes of *Acanthamoeba* (T1–T22) have been reported worldwide (Taher et al., 2018). The genotypes of *Acanthamoeba* are identified based on variation in the nucleotide sequences of the 18S rRNA gene using PCR assays (Behera et al., 2016; Schroeder et al., 2001; Booton et al., 2005). Some genotypes of *Acanthamoeba* have been associated with human infections. Genotypes T2–T6, T10, T11 and T15 have been associated with AK, while genotypes T1, T2, T4, T5, T10 and T12 have been associated with GAE (Behera et al., 2016). Various studies have shown that genotypes T3, T4, and T5 are highly

Fig. 1 Morphological structures of *Acanthamoeba*.

pathogenic to humans (Walochnik et al., 2000). Genotype T4 is the most common causative agent of AK and GAE worldwide that could be due to its greater virulence and enhanced transmissibility as well as its reduced susceptibility to chemotherapeutic agents (Ledee et al., 2009; Adamska et al., 2014). *Acanthamoeba* spp. has been commonly identified in natural environment as well. The pathogenic genotypes T4 and T12 have been frequently isolated from water samples (Haniloo et al., 2017; Lass et al., 2014; Gavarane et al., 2018). Genotype T15 has been isolated from moist, dry and aquatic samples (Basher et al., 2018). Recently identified genotypes are environmental genotype T19 (*Acanthamoeba micheli*), pathogenic genotype T20 and T21–T22 (Corsaro et al., 2015; Fuerst et al., 2015).

Human infections caused by *Acanthamoeba*

Acanthamoeba spp. causes infection among humans, with high mortality in spite of low incidence (Diaz, 2010). *Acanthamoeba* is a well-known causative agent of AK and GAE among immunocompetent as well as immunocompromised individuals (Kot et al., 2018a). AK is a severe vision threatening infection of the cornea (Lorenzo-Morales et al., 2015). It mostly occurs in contact lens wearers; however, infections have also been reported in non-contact lens wearers (Lorenzo-Morales et al., 2015). Common clinical symptoms associated with AK include redness, massive pain, tearing, photophobia, ring-like stromal infiltrate, epithelial defect and lid edema (Lorenzo-Morales et al., 2015). Lack of timely treatment of AK can lead to loss of vision (Clarke and Niederkorn, 2006; Marciano-Cabral and Cabral, 2003; Khan, 2009, 2006; Rocha-Azevedo et al., 2009; Visvesvara et al., 2007). The risk factors associated with AK include use of contact lens for extended period of time, inappropriate cleaning of contact lens, lack of personal hygiene, biofilm formation on contact lenses and exposure to contaminated water.

Acanthamoeba causes rare yet lethal infections among immunocompromised individuals known as GAE with mortality rate up to 98% (Abd et al., 2009). It usually occurs among patients with human immunodeficiency virus (HIV) infection, or among those who are on immunosuppressive drugs, antibiotics or chemotherapeutic treatment (Gonzalez et al., 1986; Carter et al., 2004; Vernon et al., 2005; Duarte et al., 2006). It has also been reported among immunocompetent individuals (Kalra et al., 2020). The symptoms of GAE usually start with headache, nausea, irritability, dizziness and low grade fever. Other neurological symptoms include, altered mental state, focal neurologic signs, diplopia, cranial nerve palsies, ataxia, high grade flaccid paralysis of right lower limb, lethargy, stiff neck and personality changes (Coven et al., 2017; Ghadage et al., 2017; Sutcu et al., 2018; Harrison et al., 2018).

Pathogenesis

As regards AK, the pathogenesis of infection starts with adhesion of pathogen to the surface of the host tissue (Panjwani, 2010). Several adhesins including mannose-binding protein, 28.2 and 55 kDa laminin-binding proteins have been identified in *Acanthamoeba* (Garate et al., 2004; Hong et al., 2004; Rocha-Azevedo et al., 2009). Various studies have revealed that the mannose-binding protein (400 kDa) of *Acanthamoeba* mediates its adhesion to the surface of the cornea (Garate et al., 2006a, 2004, 2005, 2006b). *Acanthamoeba* adheres to the mannose-containing glycoproteins of corneal epithelial cells that produce amoeba-induced cytopathic effects in mannose dependent manner (Cao et al., 1998). After mannose mediated adhesion, amoeba secretes enzymes such as neuraminidase and proteases that lead to colonization of the parasite and degradation of basal membranes, respectively (Siddiqui and Khan, 2012a; Lorenzo-Morales et al., 2015). Serine proteases induce degradation of keratocytes, retinal pigment epithelium, corneal epithelium and endothelial cells (Lorenzo-Morales et al., 2015). Proteases cause damage in the cornea stroma with inflammatory reactions, oedema and necrosis (Kot et al., 2018b).

The pathogenesis of GAE is not fully understood. Trophozoites of *Acanthamoeba* migrate to the CNS through the nasal mucous membrane, endothelium of the brain capillaries and the ethmoid bone along the olfactory nerves (Khan and Siddiqui, 2011).

Host immune response

Infection due to *Acanthamoeba* induces both innate and adaptive immunity in the host (Cano et al., 2017). Toll like receptors (TLRs) play an important role in recognizing *Acanthamoeba* spp. infection and inducing cytokine production in the host (Ren and Wu, 2011). Studies have reported increased mRNA expression of TLR2 and TLR4 in the lungs and brain of mice and cornea of hamsters infected with *Acanthamoeba* (Derda et al., 2016; Wojtkowiak-Giera et al., 2016; Alizadeh et al., 2014). The complement cascade shows activity against protozoa; however, it is not fully understood in *Acanthamoeba*. The in vitro studies have demonstrated lytic activity against *Acanthamoeba* spp. in the presence of phagocytes (Ferrante and Rowan-Kelly, 1983). However, trophozoites of *Acanthamoeba* express regulatory proteins which inhibit the complement cascade (Toney and Marciano-Cabral, 1998). The secretions of pro-inflammatory cytokines like TNF- α , IL6 from monocytes and macrophages activate neutrophils and vascular endothelial cells (van Klink et al., 1993; Benedetto et al., 2003; Stewart et al., 1994). It has been shown that TNF- α can induce the encystation of *Acanthamoeba* leading to the resistance towards phagocytosis (Mattana et al., 2016). In vivo studies demonstrated the presence of neutrophils in the brain and retina of the eye, which may inhibit the spread of invasion to other organs of the body (Harrison et al., 2010). Significant increase of natural killer cells has also been observed in mice infected with *Acanthamoeba* (Kim et al., 2012). Animal studies have been conducted to study the adaptive immune response against *Acanthamoeba*. T helper lymphocytes and regulatory T lymphocytes were observed in the cornea and atopic lymph nodes of AK mouse model. A study demonstrated that *Acanthamoeba* spp. also induces IL-17A, which relieves the symptoms of ocular infection (Suryawanshi et al., 2015). Recent study demonstrated that *Acanthamoeba* spp. induced expression of mediators such as cyclooxygenase-1 (COX-1) and

COX-2 proteins in the lungs of immunocompetent mice but a decrease in immunocompromised mice (Lanocha-Arendarczyk et al., 2018).

Diagnosis

Diagnosis of AK is often challenging as it can be easily confused with viral or fungal keratitis (Lorenzo-Morales et al., 2015; Page and Mathers, 2013; He et al., 2016). Early diagnosis is the key to a good prognosis. Samples for diagnosis of AK include corneal scraping or biopsy and contact lenses, which are stored in sterile saline (PBS or 0.9% NaCl) in order to prevent its desiccation (Lorenzo-Morales et al., 2015). *Acanthamoeba* trophozoites and cysts can be stained using silver staining, lacto phenol cotton blue, acridine orange, calcofluor white, haematoxylin and eosin (HE) and Immuno stains (Lorenzo-Morales et al., 2015). Samples with high density of *Acanthamoeba* can be detected by direct microscopy (Winchester et al., 1995). However, noninvasive and highly sensitive confocal microscopy (CF) is the preferred diagnostic technique with specificity and sensitivity higher than 90% (Winchester et al., 1995). The advantage of CF is that it can image layers within the cornea (Winchester et al., 1995; Vaddavalli et al., 2011). The trophozoites or cysts can also be readily recognized using phase contrast microscopy in which cysts appear as hyper-reflective, spherical structures of double wall (Lorenzo-Morales et al., 2015). CF and clinical suspicion can aid in presumptive diagnosis; however, definitive diagnosis of AK is based on in vitro culture, histology or molecular methods. Culture based identification of *Acanthamoeba* involves inoculation of sample on 1.5% non-nutrient agar (NNA) medium seeded with heat inactivated *Escherichia coli*. Inoculated plates are incubated at 30 °C and screened daily for amoebae using inverted microscopy. In high density samples, amoebae can be easily visible after 24–48 h of incubation. Samples should be observed for at least 1 week to give a negative result. Sub-culturing of positive samples can be done by transferring small piece of agar with few cysts on it upside down to a fresh plate (Lorenzo-Morales et al., 2015). *Acanthamoeba* can also be cultured axenically in peptone-yeast extract glucose (PYG) media. Molecular methods including polymerase chain reaction (PCR) and multiplex real-time PCR methods have been extensively used for the diagnosis of AK (Lehmann et al., 1998; Schroeder et al., 2001; Khan, 2006; Siddiqui and Khan, 2012a). In addition, matrix assisted laser desorption-ionization time-of-flight mass spectrometry and ¹H NMR (Nuclear magnetic resonance) spectroscopy has the potential to identify *Acanthamoeba* in the clinical samples (Siddiqui and Khan, 2012a).

Brain image analysis based on computed tomography (CT) and magnetic resonance imaging (MRI) is often adopted for diagnosis of GAE (Schumacher et al., 1995). Microscopic examination of cerebrospinal fluid (CSF) can be done; however, trophozoites can be easily confused with monocytes, polymorphonuclear leucocytes and macrophages (Alkhunaizi et al., 2013). *Acanthamoeba* can be cultured axenically as well as xenically by inoculating CSF/brain biopsy sample in PYG and 1.5% NNA media, respectively (Duggal et al., 2017). Histopathological examination of frozen and paraffin-embedded brain biopsy tissue can be done using Giemsa-Wright, HE, acridine orange or calcofluor white stain to identify trophozoites or cysts of *Acanthamoeba* (Kalra et al., 2020). Molecular techniques are being used for confirmative diagnosis of GAE due to *Acanthamoeba* spp. (Walochnik et al., 2015; Qvarnstrom et al., 2006).

Naegleria

Morphology

Naegleria is a free living, pathogenic amoeba. It exists in three distinct phenotypes namely, the resting cyst, a swimming flagellate, and the active multiplying trophozoites depending on the environmental conditions (Siddiqui et al., 2016). Under favorable conditions, reproductively active trophozoites of size 22 µm in length and 7 µm exists (Siddiqui et al., 2016). The trophozoites have a large nucleus with nucleolus, mitochondria, food vacuoles, contractile vacuole, endoplasmic reticulum, ribosome and membrane-bound cytoplasmic organelles. The locomotory rate of trophozoites is 45 µm/min at 37 °C (Carter, 1970). The flagellate stage exists in non-nutrient stage; but water is present (Siddiqui et al., 2016). The flagellates are pear-shaped and possess two flagella of equal length, a nucleus in the narrower anterior region and cytostome is absent. The cysts are formed in the presence of adverse or unfavorable environmental conditions. The size of cyst usually ranges between 7 and 15 µm in diameter (Maciver et al., 2020). Each cyst possess one to two mucoid-plugged pores, through which trophozoites emerge (John, 1982). *Naegleria* feeds on bacteria, algae and yeast, and can tolerate temperatures up to 45 °C (Yoder et al., 2012; Visvesvara et al., 2007).

Genotypes of *Naegleria*

The genus *Naegleria* consists of 47 pathogenic as well as non-pathogenic species that are often found in aquatic environment and soil habitats (De Jonckheere, 2002). Internal transcribed spacer (ITS) sequence of ribosomal RNA (rRNA) gene has been used to classify species of *Naegleria* (De Jonckheere, 2002, 2004). Among all the species, *N. fowleri* is pathogenic to humans (Siddiqui et al., 2016). Genome of *N. fowleri* is diploid (66 MB) and the haploid genome size is 29.62 MB (Zysset-Burri et al., 2014). The nuclear DNA of *Naegleria* is about 0.2–0.3 pg/amoeba (Byers, 1986).

Primary amebic meningoencephalitis (PAM)

The causative agent of this fatal infection of brain is *N. fowleri*. PAM is a rare yet fatal human disease with mortality rate of 95–97% (Baig and Khan, 2014). It occurs among immunocompetent children, young adults as well as immunocompromised patients and causes lethal, necrotizing, fulminant and hemorrhagic meningoencephalitis among them (Gupta et al., 2015). The incubation period after exposure to the parasite varies from 1 to 16 days. The symptoms include sore throat, fever, blocked nose, headache, stiff neck, altered taste and smell perception, changed mental status, seizures and coma that results in fatality (Siddiqui et al., 2016; Siddiqui and Khan, 2012b; Capewell et al., 2015). Clinically, it can be easily confused with bacterial meningitis due to similarity in their symptoms (Jain et al., 2002). Till date, around 431 cases of PAM have been reported worldwide (Maciver et al., 2020). *N. fowleri* is commonly present in hot springs, ponds, freshwater lakes, rivers, untreated and under treated water supplies and untreated swimming pools (Ong et al., 2017; Miller et al., 2018). PAM occurs in individuals who have been exposed to contaminated water through recreational activities such as swimming, diving or water skiing in recent past (Siddiqui et al., 2016; Grace et al., 2015).

Pathogenesis

N. fowleri enters the human host through the nose after exposure to contaminated water. The parasite is splashed or forced through the nasal cavity. It attaches to the nasal mucosa, followed by locomotion through the olfactory nerve and cribriform plate to gain entry to the brain (Siddiqui et al., 2016). The protist reaches the olfactory bulb within the CNS and causes hemorrhage and inflammation (Jarolim et al., 2000). Leptomeninges become congested, diffusely hyperaemic with limited infiltration and focal demyelination in spinal cord and white matter of the brain has been observed (Viriyavejakul et al., 1997). Virulence factors associated with the pathogenesis of *N. fowleri* are broadly categorized into contact dependent and contact independent mechanisms (Siddiqui et al., 2016). Contact dependent mechanisms include a fibronectin binding protein (60 kDa) and protein kinase C, which have been reported in *N. fowleri*. These play a role in binding to and cytotoxicity of host cells (Han et al., 2004). After binding to host cells, sucker-like surface structure protruding from the surface of *N. fowleri* aids in gradual consumption of target cells. Phagocytosis and amoebastome lead to *N. fowleri* mediated host cell damage (Tiewcharoen et al., 2014). Contact-independent mechanisms based on pore forming proteins (N-PFP) and hydrolytic enzymes contribute to the pathogenicity of *N. fowleri*. *N. fowleri* releases phospholipases, sphingomyelinase, lysophospholipase which cause damage to lipid-rich cytoplasmic membrane of the cell and demyelinate nerve tissue (Ferrante and Bates, 1988).

Host immune response

Upon exposure to *N. fowleri*, activation of innate defence mechanism occurs in the respiratory epithelial cells. This activation broadly includes the inflammation (IL-8 and IL-1 β) and mucin secretion by the production of reactive oxygen species (Cervantes-Sandoval et al., 2009). Mucin inhibits the binding of *N. fowleri* to cells and cytotoxicity in vitro and in vivo. Neutrophils and eosinophils have been observed in later stages of infection. Knockout mice experiments have demonstrated that host polymorphonuclear (PMN) cell lysis action and inflammatory response leads to the damage of CNS tissues (Siddiqui et al., 2016). In vitro study on interaction of PMNs with trophozoites of *N. fowleri* demonstrated that trophozoites induced formation of neutrophils extracellular traps that inactivate and catch the pathogen (Contis-Montes de Oca et al., 2016). The activated macrophages such as Microglial cells act against the invasion of CNS by *N. fowleri* (Vyas et al., 2015). They induce production of nitric oxide and arginine-dependent cytolytic mechanism to kill *N. fowleri*.

Diagnosis

The diagnosis of PAM is difficult as it follows a rapid course. Usually diagnosis is made on histopathological examination of tissue obtained post-mortem. A high suspicion of PAM is deemed after CSF culture is negative for bacteria. CSF sample collection may cause brain herniation due to high intracranial pressure in patients with PAM (Visvesvara, 2013). Nasal secretions from the primary site of infection can be collected for the identification of *N. fowleri* (Baig and Khan, 2015). Wet mount preparations may show motile trophozoites. Trophozoites of *N. fowleri* have also been identified in the CSF using trichrome or Giemsa staining (Visvesvara and Maguire, 2006). *N. fowleri* has been identified in the culture of CSF and nasal secretions of PAM patients (Singh et al., 1998). Molecular techniques such as PCR and nested PCR have been used to identify *N. fowleri* in cultured amoebae from patients (Marciano-Cabral and Cabral, 2003; Zhou et al., 2003). Real time multiplex PCR has been used to identify *N. fowleri* in the CSF and brain tissue samples from PAM patients ante mortem (Qvarnstrom et al., 2006).

Balamuthia mandrillaris

Morphology

B. mandrillaris exists in two distinct morphological structures including a vegetative trophozoite and a dormant cyst. The size of trophozoites varies from 12 to 60 μ m in diameter. They are uninucleate; however, binucleate forms have also been reported

(Visvesvara et al., 2007). The nucleus contains two or three large, centrally placed nucleoli and cytoplasm contains numerous mitochondria, ribosomes and endoplasmic reticulum. Trophozoites reproduce asexually by binary fission and also form pseudopodia (Jayasekera et al., 2004, 2005; Schuster and Visvesvara, 2004). Under hard conditions such as extremes in pH, temperatures and lack of food, trophozoites transform into a cyst stage. The cysts are uninucleate, more or less spherical and their size varies between 12 and 30 μm . Cysts of *B. mandrillaris* have three layers including an outer, irregular ectocyst, a thick endocyst and a middle nebulous mesocyst (Visvesvara et al., 2007). Both forms of *B. mandrillaris* can enter the human body through nasal passages to the lower respiratory tract and wounded skin Fig. 2.

Granulomatous amebic encephalitis

B. mandrillaris is one of the possible causative agents of GAE among both immunocompetent and immunocompromised patients (Siddiqui and Khan, 2008). GAE due to *B. mandrillaris* clinically resembles viral or bacterial meningitis, leptomeningitis and tuberculous meningitis (Siddiqui and Khan, 2008). The clinical symptoms include fever, headache, skin lesions, nausea, vomiting, acute confused state, photophobia, cranial nerve palsies, increased intracranial pressure, seizures, brain edema and death (Jayasekera et al., 2004; Schuster and Visvesvara, 2004). Brain images of patients with GAE caused by *B. mandrillaris* demonstrate ring enhancing lesions (Siddiqui and Khan, 2008). GAE due to *B. mandrillaris* has a slow onset, which takes months and years to develop into a sub-acute and chronic disease. However, organ transplant recipients have a rapid clinical course (Farnon et al., 2016). Till date, approximately 200 cases of *B. mandrillaris* amebic encephalitis have been reported worldwide (Takei et al., 2018). Males are 2.5 times more susceptible to this infection than females as they are more exposed to soil (Diaz, 2011). Patients with HIV/AIDS, diabetes mellitus, liver disease or cancer and those on immunosuppressive drugs, and alcoholics are at high risk of infection (Takei et al., 2018; Siddiqui and Khan, 2008). Contaminated soil is the major risk factor for contracting GAE (Dunnebacke et al., 2004; Schuster et al., 2003).

Pathogenesis of GAE caused by *Balamuthia mandrillaris*

It is not completely understood. *B. mandrillaris* colonizes the skin lesions or nasopharynx and enter into the intravascular space. These parasites then survive within the blood stream and invade the CNS. This leads to brain tissue damage and ultimately meningoencephalitis (Siddiqui and Khan, 2008). Amoeba can invade the nasal mucosa and migrate along the nerve fibers, followed by invasion of the olfactory bulb (Kiderlen and Laube, 2004). Amoebae invade the CNS at the site of blood brain barrier (Schuster and Visvesvara, 2004). Therefore, *B. mandrillaris* adhesions, protease activity, blood brain barrier injury or host inflammatory response can disrupt the blood-brain barrier. *B. mandrillaris* through galactose binding protein on their surface binds to the human brain microvascular endothelial cells (Matin et al., 2006). The pro-inflammatory cytokines like TNF- α , IL-1 along with IL-6, IL-8 and granulocyte/macrophage colony stimulating factor increase the permeability of blood-brain barrier (Leib and Tauber, 1999). Studies have reported that *B. mandrillaris* exhibits proteolytic activities to degrade extracellular matrix that leads to the invasion of and growth in the brain tissue (Matin et al., 2006; Rocha-Azevedo et al., 2007).

Immune response

Antibodies (IgG and IgM) with titres ranging from 1:64 to 1:256 against *Balamuthia* have been identified in the sera of healthy individuals as well those with *Balamuthia* GAE (Visvesvara, 2010; Visvesvara et al., 2007). The presence of antibody in humans could be due to the exposure to these ubiquitous amoebas in the environment (Visvesvara, 2010).

Fig. 2 Life cycle of *Balamuthia mandrillaris*.

Diagnosis

Diagnosis of GAE caused by *B. mandrillaris* is challenging as the symptoms of the infection may be non-specific. In patients from Peru, skin lesions especially the central face plaque (nose lesion) is the best clue for diagnosing *Balamuthia* GAE (Bravo et al., 2011). Neuroimaging findings based on CT and MRI are often non-specific and reflect lesions with surrounding edema (Lorenzo-Morales et al., 2013a). However, evidence of intralésional hemorrhage is an important clue for diagnosis (Visvesvara et al., 2007; Kiderlen et al., 2008). *B. mandrillaris* can be detected in brain or skin biopsies either by immunofluorescence or immunoperoxidase staining with rabbit anti-*Balamuthia* sera in paraffin-fixed tissue (Visvesvara et al., 2007; Guarner et al., 2007). However, these tests are available at CDC, United States. Other serological tests such as ELISA and flow cytometry assays are there; however, it requires careful interpretation as healthy individuals may have positive serology. Molecular techniques including PCR, real-time multiplex PCR have been used to identify *Balamuthia* DNA in human CSF and brain tissue samples (Tavares et al., 2006; Yagi et al., 2005; Qvarnstrom et al., 2006; Schuster et al., 2003; Niyiyati et al., 2009).

Sappinia pedata

Sappinia are coprozoic amoebas that exist as a feeding trophozoite and a dormant cyst form. The trophozoites are ovoid or oblong with occasional wrinkles on their surface. Their size varies from 40 to 80 µm. Trophozoites are binucleate with two tightly opposed nuclei and its cytoplasm contains food vacuoles and a contractile vacuole (Visvesvara, 2013). The cysts are round in shape and size measures 15 to 30 µm in diameter. They are also binucleate with two tightly opposed nuclei. The first and only case of amebic encephalitis caused by *S. pedata* (earlier identified as *S. diploidea*) was diagnosed based on the nuclear morphology of the amoeba (Gelman et al., 2001). GAE due to *S. pedata* occurred in an immunocompetent individual who presented with nausea, vomiting, bifrontal headache, photophobia, and blurry vision that lasted for 2–3 days. MRI findings revealed a 2 cm mass in the posterior left temporal lobe with ring enhancement. Microscopic examination of the excised mass showed necrotizing hemorrhagic inflammation containing amebic trophozoites with double nuclei (Gelman et al., 2001). *Sappinia* spp. can be identified by molecular techniques including PCR and real-time PCR.

Treatment

Treatment of *Acanthamoeba* keratitis

As of now, no single drug can be used to eradicate both cystic or trophozoite forms. Trophozoites are more susceptible to elimination by drugs (Lorenzo-Morales et al., 2013b). Treatment of AK relies upon topical agents like biguanides and chlorhexidine in combination with aromatic diamidines. Both biguanides and chlorhexidine increase the cytoplasmic membrane permeability. These drugs are positively charged and bind negatively charged phospholipids of cellular membrane leading to cell lysis. Biguanides like polyhexamethylene biguanide or PHMB, though effective at low concentrations (0.02%), may cause toxic keratopathy. Chlorhexidine (0.02%) with diamidines like 0.1% propamidine isethionate, 0.15% dibromopropamidine, hexamidine 0.1% have also shown good results (Lorenzo-Morales et al., 2015; Roberts and Henriquez, 2010). These topical agents are given after corneal debridement for several days. Treatment duration can extend up to 3–4 weeks. Corneal transplantation may be done if treatment fails and cornea has been damaged in acute phase of infection (Lorenzo-Morales et al., 2013b, 2015). Therapeutic penetrating keratoplasty may be considered when infection involves paracentral cornea despite antiamebic therapy (Cohen et al., 1987; Hamburg and De Jonckheere, 1980). Medical treatment should be continued even after surgery for several months to ensure successful elimination of *Acanthamoeba*. In such cases, prognosis is poor (Lorenzo-Morales et al., 2015). In addition to the current therapeutic approach, various researchers are also investigating the effectiveness of nanoparticle conjugated drug against *Acanthamoeba* (Sharma et al., 2020).

Treatment of Granulomatous amebic encephalitis due to *Acanthamoeba* species, *Balamuthia mandrillaris* and *Sappinia pedata*

The successful treatment relies upon an early diagnosis. Usually, skin lesions precede CNS symptoms by weeks to months. The combination of surgical resection of lesions and multiple antibiotics like pentamidine, cotrimoxazole, propamidine isethionate, azoles like fluconazole, itraconazole and voriconazole, amphotericin B, flucytosine, rifampin, azithromycin, amikacin have been tried. In >90% of successfully treated cases of GAE, miltefosine, azoles, pentamidine, and cotrimoxazole were used. A major concern is side effects of pentamidine and low permeability of pentamidine among HIV infected patients (Orozco et al., 2011; Parija et al., 2015).

Treatment of primary amebic meningoencephalitis due to *Naegleria fowleri*

No clinical trials have been conducted to assess the treatment options among humans. The most commonly used agent for treatment of PAM is Amphotericin B. Other agents mentioned in literature are fluconazole, miconazole, azithromycin, miltefosine and rifampin (Kim et al., 2008; Goswick and Brenner, 2003). Amphotericin B is given intravenously or intrathecally. Centers for

Table 1 Therapeutic management of patients diagnosed with *Acanthamoeba* keratitis, primary amebic meningoencephalitis and granulomatous amebic encephalitis.

Disease entity	Medical treatment	Dose	Duration
<i>Acanthamoeba</i> keratitis			
<i>Acanthamoeba</i> species	Biguanides like polyhexamethylene biguanide (0.02%) and chlorhexidine (0.02%) in combination with diamidines like propamidine isethionate (0.1%) and hexamidine isethionate Antifungals like ketoconazole given topically in a concentration of (1%) in combination with biguanides If topical therapy fails, keratoplasty or corneal transplantation Novel agents like alkylphosphocholines e.g., Miltefosine	Topical therapy after corneal debridement: Chlorhexidine and propamidine Given hourly for initial 3 days than 3 hourly	For a total of 3–4 weeks to 6–12 months
Primary amebic meningoencephalitis			
<i>Naegleria fowleri</i>	Conventional Amphotericin B	Given intravenously in a dose of 0.25–1.5 mg/kg/day in adults and 0.5–0.7 mg/kg/day in children in two divided doses for 3 days followed by 1 mg/kg/day once daily for 11 days OR Intrathecal in a dose of 1.5 mg/kg/day for 2 days followed by 1 mg/kg/day for 8 days	Intravenous regimen for 14 days and intrathecally for 10 days
	Miltefosine	50 mg orally two to three times daily with maximum dose of 1.5 mg/kg/day	28 days
	Adjunctive therapy with Fluconazole	Given in combination with Amphotericin B Intravenously in a dose of 10 mg/kg/day once daily	28 days
Granulomatous amebic encephalitis			References
<i>Acanthamoeba</i> spp.	Multiple antibiotics given in combination	Successful treatment has been done with combination of drugs like rifampicin, cotrimoxazole, fluconazole, albendazole and ceftriaxone	Khanna et al. (2014)
<i>Balamuthia mandrillaris</i>		Prolonged therapy (upto years) with combination of agents like Pentamidine, Miltefosine, fluconazole, flucytosine and albendazole, sulfadiazine has been tried successfully	Vollmer and Glaser (2016)
<i>Sappinia diploidea</i>		Azithromycin, Pentamidine, Itraconazole and Flucytosine have been used successfully	Gelman et al. (2001)

Disease Control and Prevention (CDC) recommends use of conventional amphotericin B 1.5 mg/kg/day in two divided doses intravenously for 3 days that is followed by 1 mg/kg/day once daily for next 11 days. Intrathecal regimen consists of 10 days of treatment with conventional amphotericin B (CDC, 2014). Another drug recommended by CDC for treatment of infections caused by FLA including *N. fowleri*, *Acanthamoeba* species and *B. mandrillaris* is miltefosine. The recommended dose is 50 mg orally two to three times daily for a total of 28 days (CDC, 2013) Table 1.

Prevention

The predominant risk factors associated with AK infection includes contact lenses and lens care solution. Therefore, contact lenses and lens care solutions should be kept clean. Individuals should remove contact lenses while swimming and performing other water activities. Soap based hand washing should be performed before handling contact lenses. Periodic inspection of hot water tanks, Jacuzzis, filters used in heating, ventilating and air conditioning units is strongly recommended as *Acanthamoeba* can easily grow and colonize them. *N. fowleri* proliferates in less chlorinated water at ambient temperature above 30 °C. Therefore, chlorine levels should be maintained in the water of swimming pools especially in summers. Untreated water should be avoided for nasal rinsing. Cases of *Balamuthia* have been associated with contamination of wound after contact with soil.

Introduction

The term helminths (from the Greek helmins that simply means worm) includes Annelida, Acanthocephala, Platyhelminthes, Nematoda, and Pentastomida, parasites extremely varied as far as anatomical organization, and very different from the phylogenetic point of view (Melhorn, 2001). However the term, nevertheless bit aspecific, is very useful and used as it encloses in a single word many species of medical and veterinary interest.

Differently from Protozoa (unicellular eukaryotes in which each cell has to be able of survive, live and reproduce), helminths are pluricellular eukaryotes (Metazoa) in which the many cells are well organized in a highly integrated functioning, with the development of fully specialized organs. Differently from Protozoa and like all macroparasites, helminths are characterized by the following features: have long time of sexual maturation; reproduce giving progeny not similar to itself, but disseminative elements often inactive; their number in the host do not increase (except in opportunistic species), being each individual the result of a new infection; remain in the host many years but, as they do not elicit permanent immunity, reinfections are possible; tend to be overdistributed in the population: most subjects have a low parasitic burden, and few individuals harbor many specimens, as effect of environmental, behavioral, and parasitic factors, but also a feature partially under genetic control and related to specific chromosomal regions (Williams-Blangero et al., 2002).

As proven by paleoparasitology, systematics, biology, biochemical and molecular studies, the mankind faces helminths from prehistory to present age. Therefore, the knowledge of helminth fauna throughout the years, largely recorded around the world, is allowing progress toward understanding changes occurred during the late Pliocene and Quaternary (as episodic shifts in climate, habitat, and ecological structure), and parasite relationships to global public health (Hoberg et al., 2012; Zarlenga, 2014). For example, a recent review about the origin of human parasites (Araújo et al., 2013) denied the common knowledge that intestinal helminths have been introduced to America by African slaves: they already existed in American prehistoric populations (Fornaciari and Gaeta, 2014).

The medically most important species belong to two phyla: Platyhelminthes (flatworms) and Nemathelminthes (roundworms), which infect approximately 25% of the world population mostly living in developing areas of sub-Saharan Africa, Asia, and the Americas. Here, one-third of the almost 3 billion people are parasitized by one or more species, which are responsible for substantial morbidity to 100–150 million people, and for more than 14 million of disability-adjusted life years due to disability plus mortality (Global Burden of Disease 2010 Project) (GBD; WHO, 2008). Therefore, helminths have an enormous impact on the life quality, mainly considering the many chronic and disabling infections by them induced. Finally, they affect also livestock, worsening malnutrition in poor countries and allowing the establishment of further parasitic diseases. Notwithstanding their impact on the health, helminth diseases continue to be among the neglected tropical diseases and, despite all medical and veterinary interventions, they remain a substantial problem for people, their domestic food animals, and wild vertebrates (Fenwick, 2012).

Among the 75,000–300,000 species of helminths that globally infect terrestrial and aquatic vertebrates (Dobson et al., 2008), about 300 are reported in humans (Cleaveland et al., 2001; Ashford and Crewe 2003; Kuris 2012), with 83 as prevalent. Apart from

many species that require further elucidation, only 39 species are considered anthropoparasites (totally dependent on humans for their transmission), whereas about 20 are considered zoo-anthropoparasites (with vertebrates, humans included, as final hosts, and people possibly involved in the parasite circulation but not required for its transmission) as occurs in *Trichuris trichiura*, *Paragonimus westermani*, *Diphylobothrium latum*, or species of the genus *Trichostrongylus* (Cancrini et al., 1982; Ashrafi et al., 2020). Finally, about 160 species are considered zooparasites as they have vertebrates different from humans as final host, and humans are not involved in their transmission or circulation. People, accidentally infected by eggs or larval stages of these zoonotic species, being unsuitable hosts, mostly block the full development. It happens in some tapeworms (as *Dipylidium caninum*, and species of the genus *Echinococcus*), and flukes (as *Schistosoma bovis*, and species of the genus *Trichobilharzia*) (Polley, 2005; Kuris, 2012). As far as roundworms, larval stages went into humans may have three different outcomes: they can be blocked in tissues if the cycle of the species includes paratenic (=transport) hosts, that is vertebrates in which the parasite merely remains viable without develop or multiply (as happens in *Parastrongylus cantonensis* and in species of the genus *Gnathostoma*, *Gongylonema*, *Anisakis*, *Pseudoterranova*, and probably also *Contracoecum* and *Hysterothylacium*); in absence of usual paratenic hosts, they long and actively migrate at cutaneous (species of the genus *Ancylostoma*, *Afrancylostoma*, *Uncinaria*, *Dirofilaria*), or visceral (*Toxocara*, *Parascaris*, *Toxascaris*, *Baylisascaris*), ocular (*Toxocara*, *Dirofilaria*), or encephalic (*Toxocara*, *Setaria*, *Dirofilaria*) levels; they become not reproducing adults (as happens in *Parastrongylus costaricensis*, and species of the genus *Spirocerca*, *Calodium*, *Dirofilaria*). *Dirofilaria repens* is an example of the tangible biological event regarding possible changes in host adaptation, as in few cases not only adult females, but also circulating microfilariae have been reported (Nozais et al., 1994; Petrocheilou et al., 1998; Supriaga et al., 2004; Fontanelli Sulekova et al., 2016). That means not only the presence of a male worm (often not detected because too small) but also that both worms survive long enough to reach sexual maturity and mate. The same has been reported in *Brugia* infections (Greene et al., 1978; Baird et al., 1986) and in a *Dipetalonema*-like infection (Simmons et al., 1984).

From these data we can infer that human infection by helminths often means the presence of parasitized animals and, consequently, attendance of habitats devoted to livestock or used by wild/company animals or, finally, poor food security/hygiene, and poor hygienic habits (Daszak et al., 2000; Lafferty et al., 2008). Of course these elements act as opportunity (not cause) of infection, however the complexity of biological cycles primarily suggests a more strict correlation with all components of any ecosystem, geographic, climatic and anthropic included. Actually, helminth diseases go with humans throughout the history, as their geographic expansion starts with hominid expansion, and become a major problem with changes then occurred: rapid increasing of sedentary human population, development of agriculture, animal domestication, slave trade, colonial occupations. Currently parasitic diseases are an emergence mostly due to anthropogenic drivers as environmental modifications, urbanization and industrial revolution (Daszak et al., 2000; Patz et al., 2008; Rosenthal, 2009; Hoberg, 2010; Kuris, 2012). These challenges between people and the biosphere have also upset the climate: temperature and humidity, important limits for any possible cycle, are now favoring the spreading of soil-transmitted and vector-borne diseases in areas to date inapt to the development of geohelminths or filarial worms (Cancrini and Gabrielli, 2009). The geographic pattern of helminth diseases may be also influenced by the disruption of socioeconomic controls on infections due to wars, by movement of refugees (Patz et al., 2008; Weaver et al., 2010; Zarlenga et al., 2014) and, more recently, by the application of medical interventions that require administration of immunosuppressive drugs (Muñoz et al., 2011; Chokkalingam Mani et al., 2013; Iori et al., 2014). Improved diagnostics and therapeutics, and preventive strategies started since 1909 (a hookworm eradication campaign, applied to 53 countries on six continents) (Fosdick, 1952) have affected only partially distribution and outcomes of helminth diseases (Savioli et al., 2004; Macchioni et al., 2015; Spinicci et al., 2018; Errea et al., 2019; Della Bella et al., 2020). In general poverty limits effective implementation of control strategies (Macchioni et al., 2016); it is a true primary social barrier to health, expressed as low- and middle-income, lack of safe drinking water, overcrowding, hygienic-sanitary precarious conditions of people and, at personal level, working activity and hygienically erroneous behaviors (as utilization of feces as fertilizer, and their environmental dispersal), all factors particularly influent in the helminth spreading.

Although the most important helminths (flatworms and roundworms) evolutionarily diverged many hundreds of millions years ago, their patterns of infection and transmission are similar, as also pathogenesis and host immune responsiveness, which is dominated by a Type 2 (Th2) profile with a significant regulatory (Treg) function (Bruschi et al., 2013). However helminth species considerably vary in virulence, prevalence, abundance, and pathogenicity (Kuris, 2012), and are etiological agent of many major tropical diseases.

As far as the helminth classification, the number and types of characters and methodologies (historical, phylogenetic, biological, biochemical and genetic) used to define the concept of species is now more convoluted than in the past (Brooks and McLennan, 2002; Wiley and Lieberman, 2011), thus the establishment and validation of flatworms and roundworms is still a matter of controversy (Zarlenga, 2014). The only groups that are today fairly stable are the phyla, the families, and the species (Melhorn, 2008), therefore they are the only taxa reported in this chapter.

As regards drugs used against helminths, the treatment of specific parasitic infections is addressed in detail in other chapters of this Encyclopedia, therefore this chapter will set only very basic information related to possible damages induces by each group of drugs.

Platyhelminthes

The Platyhelminthes include, in addition to free-living turbellarian, to ectoparasites and endoparasites mostly of fishes and turtles, endoparasites of medical interest (Eucestoda and Digenea) that will be here described as cestodes and digeneans.

This phylum, which collects a total of about 25,000 species, is of strategic phylogenetic importance as it includes the first bilaterally symmetrical organisms in evolution. From here the cephalization took place and the early metazoan brain began to develop; therefore Platyhelminthes constitute the basal stock from which all higher animal phyla are thought to have evolved (Melhorn, 2001).

The body of these dorsoventrally flattened worms is soft, circumscribed by a plasma membrane or tegument, bilaterally symmetrical, provided of holdfast organs. Flatworms are lacking a body cavity (coelom) and specialized organs for circulatory or respiratory systems. In their absence the permeable tegument allows the diffusion of oxygen and other nutrients. All species are oviparous, and most of them are hermaphroditic (monoecious animals). The life cycle is usually indirect (heteroxenous development): it involves a vertebrate (called final host, parasitized by sexually mature adults) and one or more species of invertebrate/usually vertebrate animals (called intermediate hosts, in which larval stages develop).

Although cestodes and digeneans share many biological and developmental characters, faunal and morphological diversity overflows.

Cestodes

Cestodes, commonly named tapeworms, are among the oldest helminths that colonized our ancestors about 2 million years ago (Hoberg et al., 2001). The earlier fossil records are in Egypt: eggs of *Taenia* dated 1198 years BC (Horne and Lewin, 1977; Harter et al., 2003), and cysticerci detected in a mummy of the II-I century BC (Bruschi et al., 2006).

A total of about 6,000 species have been to date described. Species of medical interest, grouped in families and presented as usual/possible human parasites or zoonotic species, are listed in Table 1.

Morphological and functional characteristics

Adult worms colonize, often for many years, the intestine of a vertebrate host (man included), whereas larval stages (globally called metacestodes) develop in different tissues of invertebrate hosts (exceptions: species of the genus *Taenia* and *Echinococcus*).

The body of these worms is 3 mm–12 m long, segmented, and is firmly anchored to intestinal wall by means of the acetabulate scolex supplemented with a rostellum (carrying hooks or apical gland), suckers, or bothria (wing-like sucking grooves) that make possible a very close contact with the host. The outer surface is covered by a syncytial cytoplasmic tegument that preserves the body shape, allows the uptake of nutrients (and drugs), and protects the worm against digestive enzymes and immune response of the host. The absorptive surface of the tegument is amplified by the formation of many cytoplasmic extensions (microtriches) similar to microvilli of enterocytes.

The body includes: the scolex (head, bearing specific holdfast organs well supplied with nerve plexuses), a neck (area continuously differentiating in new segments named proglottids) and the strobilus (chain of 3–4,000 proglottids: the first immature, followed by the mature ones and, at the hind end, by the gravid segments, all provided of smooth muscle fibers, nerves and excretory vessels). The complex scolex-neck is the target of therapy, inasmuch as in case of drug failure the entire worm will regrow (Fig. 1).

Tapeworms are protandric hermaphrodites, therefore each mature proglottid contains one or two sets of the complete male and female sexual apparatus that, however, do not mature at the same time (male gonads mature before those of female). Size, number and structures associated to sexual organs vary depending on the species. Testes converge in a vas deferens and cirrus (copulatory structure); the ovary releases oocytes that reach the ootype where meet spermatozoa and, with yolk cells produced by the Mehlis's and vitellary glands, become shelled eggs and move to uterus and vagina (both may also have the function of storing injected spermatozoa). Sexual organs, merged in a parenchymal tissue, converge with a genital porus; fertilization may occur either within each segment or between contiguous segments (autogamy), or between proglottids of different strobila. Last proglottids, after the obliteration of all other elements of the sexual apparatus, only present the branched uterus packed with eggs (Fig. 1). In species belonging to the order traditionally named Cyclophyllidea, groups of gravid segments from time to time actively detach (apolysis) and are voided with feces. In the environment proglottids disintegrate on impact with the weathering, and the eggs are liberated. Instead, in species belonging to the order traditionally named Pseudophyllidea each segment presents a uterine porus from which the eggs are continuously eliminated.

Table 1 Cestodes of medical interest, grouped as usual/possible pathogens for humans or zoonotic species, and their possible classification in families.

Family	Anthropoparasites and Anthro-Zooparasites	Zooparasites
Anoplocephalidae	<i>Inermicapsifer cubensis</i>	<i>Bertiella studeri</i> , <i>B. mucronata</i>
Davaineidae		<i>Raillietina demerariensis</i> , <i>R. asiatica</i> , <i>R. formsana</i>
Dilepididae		<i>Dipylidium caninum</i>
Diphyllobothriidae	<i>Diphyllobothrium latum</i>	24 species: gen. <i>Diphyllobothrium</i> , <i>Spirometra</i> , <i>Diplogonoporus</i> , <i>Schistocephalus</i> , <i>Pyramicocephalus</i>
Hymenolepididae	<i>Rodentolepis nana</i>	<i>Hymenolepis diminuta</i>
Mesocestoididae		<i>Mesocestoides lineatus</i> , <i>M. corti</i>
Taeniidae	<i>Taenia asiatica</i> , <i>T. saginata</i> , <i>T. solium</i>	13 species: gen. <i>Taenia</i> , <i>Echinococcus</i>

Fig. 1 Diagrammatic representation of a tapeworm: flattened, segmented, extremely long (3 mm–12 m) and hermaphrodite helminth. Scolex (SC) provided of suckers (SK) and rostellum (RS) armed with hooks (HK) to adhere to intestinal wall. The scolex is followed by a neck (NK) and by a chain of proglottids (continuously produced by the neck) named strobilus. The neoproducted proglottids are immature (IM), and are followed by that provided with only male reproductive organs (M), then by that with both sets of sexual apparatuses (M + F, a bit magnified) and, at the bottom, that gravid ones with a branching uterus filled of eggs (GR). Common systems: reproductive, simple nervous and excretory. Testes (TS) confluent in a vas deferens (VD); ovary (OV), ootype (OO), vitellarium (VT), uterus (UT), vagina (VG), and genital porus (GP). Cerebral ganglion (CG), from which depart longitudinal nerves (LN) present along all the body, with transverse minor ring commissures, all parallel to excretory vessels (EV) present in each segment.

Cestodes are lacking a coelom, but also digestive, respiratory, and circulatory systems. Nervous system is simple (cerebral bilobed ganglionic structures, two main longitudinal nerve cords and minor longitudinal cords connected, at intervals, by transverse minor ring commissures, well developed plexuses/nerve nets, and secretory inclusions) but very efficient. Indeed, to assure the maintenance of contact with the host, attachment organs are equipped with nerve plexuses reactive for cholinesterase, serotonin, and several neuropeptides. Moreover, in absence of coelom and circulatory system, by releasing neurosecretory or peptidergic components (as catecholamines, histamine, nitric oxide, neuropeptides, growth factors) into the intercellular space, the nervous system accomplishes any long-distance control of processes such as growth and development. In this way it also functions as an endocrine system (Melhorn, 2001). Parallel to longitudinal nerve cords and to transverse minor ring commissures, in each segment excretory vessels are sited.

Their anaerobium metabolism depends on carbohydrates that are adsorbed through the many microtriches present on the outer surface of the body. In some cases the development is conditioned by the presence of vitamins of the B group or sexual hormones.

Eggs produced contain a hooked embryo that develops into a larval stage generally named metacestode: cysticercus, or cysticercoid, or coenurus, or hydatid, or proceroid and plerocercoid (Fig. 2).

Cysticercus and cysticercoid are monosomatic larvae (they are vesicles containing only one early scolex, called protoscolex), whereas coenurus and hydatid are polysomatic (undergo a budding process that produces, respectively, many or a very large number of protoscolices invaginated in the vesicle).

Basic life cycles (Fig. 3)

The life cycle of almost all cestodes involves two or more host species, and may be very different. In detail:

- Species having a terrestrial cycle

The proglottids excreted by people/vertebrates on the soil release eggs bordered by a thick embryophore, which contain an embryo named oncosphaera or hexacanth (because six-hooked). The cycle may go on only when an intermediate suitable host ingests the eggs from the contaminated environment. The ontogenesis proceeds as metamorphosis in larval stages sometime asexually reproducing (Fig. 3A). In detail, depending on species and intermediate host, the hexacanth may develop into: cysticercus, or coenurus or hydatid (in tissues of a wide variety of terrestrial domestic or wild animals, but also humans), or cysticercoid (usually in arthropods; however, the cysticercoid development is also possible in the intestinal wall of humans

Fig. 2 Eggs and metacystodes of species having terrestrial (A) or aquatic (B) cycle. (A) (1) Egg enclosing the hexacanth (EX); (2) cysticercus, fluid-filled cyst containing a single invaginated protoscolex (PS); (3) cysticercoid, a single evaginated protoscolex embedded in a small solid cyst; (4) coenurus, fluid-filled cyst with germinal epithelium (GE) producing many protoscolices; (5) hydatid, large and growing fluid-filled cyst with germinal epithelium producing thousand of brood capsules and protoscolices, daughter and granddaughter, endogenous (EN) or exogenous (ES) cysts, very invasive. (B) (6) Egg with operculum (OP); (7) ciliated coracidium went out from the egg and supplied with 6 hooks; (8) proceroid larva, endowed with characteristic terminal rosette; (9) plerocercoid, solid-bodied larva starting the body segmentation, and showing the characteristic scolex with bothria (BO) instead of suckers.

parasitized by the adult worms) (Fig. 3B). The life cycle is completed when people/another vertebrate eats raw or undercooked meat of terrestrial domestic/wild animals parasitized by metacystodes, so allowing the development of adult intestinal worms. Monosomatic larvae will give birth to one adult worm, whereas polysomatic ones will mature in many (even a very large number) of adults. If people accidentally ingest eggs (auto- or hetero-infection), as any intermediate host will allow their development into metacystodes that will grow up and expand in any tissue.

Fig. 3 Life cycles of cestodes pathogen for humans. Development and transmission patterns of species releasing proglottids (A) or eggs (B) on the soil, and that of species having an aquatic cycle (C).

- Species having an aquatic cycle (Fig. 3C)

Proglottids produce huge number of eggs that leave the vertebrate host with the feces. Eggs are endowed of an operculum (cap like) that, only in presence of water, opens up and let out a ciliated hexacanth (coracidium). Coracidium, eaten by an aquatic arthropod, develops into proceroid and then, in the same/a second intermediate host (usually a fish), into plerocercoid larva (named sparganum). The cycle is completed if people/another vertebrate eats raw or undercooked fishes containing encysted sparganum, so developing an intestinal infection by adult worm. In case of accidental drink of water containing parasitized very small crustaceans, or following ingestion of amphibians/reptiles raw/undercooked, in vertebrate hosts proceroid or plerocercoid larvae reach tissue locations with severe consequences.

Infection, prevention, transmission

Intestinal infections are mostly due to eating habits, whereas metacestodoses have as predisposing factors poor hygienic/socio-economic conditions or the profession.

Cooking (or freezing before eating) edible meats, washing accurately vegetables before eating, drinking uncontaminated water, and accurately observing hygiene rules (washing hands before eating) are useful to prevent the infection.

People affected by adult tapeworms are source of infection for intermediate hosts and, in some cases, for himself/other people, whereas people affected by larval stages are a dead end for the parasite. To break the parasite transmission, apart the appropriate drug taking, infected people must avoid the environmental dispersal of feces, and edible meats should be controlled at public level or cooked/frozen at personal level.

Pathogenicity and drugs

In general adult cestodes deprive the host of nutrients (sometime specific substances), exert a toxic action and may cause diarrhea, decreased appetite or voraciousness, and weight loss. Moreover, they induce physical damages, both little by holdfast organs, and possibly severe in case of bowel obstruction. Adulticidal drugs used may: damage the parasite tegument exposing it to the defenses of the host (aminoglycosides as paromomycin); cause spastic paralysis of the parasite muscle cells (pyrazino-isoquinolines as praziquantel); induce energetic depletion responsible for the scolex detachment (halogenated salicylanilides as niclosamide), or starvation of the parasite (benzimidazole carbamates as albendazole and mebendazole).

Larval stages developed in tissues are more dangerous, mainly if located in the brain, lungs, liver, eye or muscles, where they can grow up and, even, rupture releasing their allergenic content. Therefore their presence exerts mechanical and allergenic actions, and may cause anaphylactic shock. Drugs used are corticosteroids associated to albendazole or praziquantel; however, may be required surgical removal of the metacestode or, depending on the developed larva, the percutaneous aspiration-injection-reaspiration (PAIR) of the content guided by ultrasound, plus albendazole treatment.

Digeneans

The oldest demonstration of digeneans in human tissues are referred to eggs of *Schistosoma*, detected in Egyptian mummies dated 1184–1087 BC (Ruffer, 1910), followed by that of *Clonorchis*, widespread in Korea and China already 2300 years ago.

Usually known as flukes, digeneans are perhaps the largest group of endoparasitic metazoan, whose species (more than 6,000) parasitize all class of vertebrates, humans included. Species of medical interest, grouped in families and subdivided as usual/possible human parasites or zoonotic species, are listed in Table 2.

Few species are intestinal parasites, whereas most are systemic: the adults colonize liver, bile ducts, gallbladder, circulatory system, and respiratory shaft. Larval stages develop in tissues of intermediate hosts (mostly aquatic).

Table 2 Digeneans of medical interest, grouped as usual/possible pathogens for humans or zoonotic species, and their possible classification in families.

Family	Anthropoparasites and Anthro-Zooparasites	Zooparasites
Dicrocoeliidae		<i>Dicrocoelium dendriticum</i> , <i>Eurytrema pancreaticum</i>
Diplostomidae		<i>Alaria americana</i>
Echinostomatidae	<i>Echinostoma echinatum</i>	21 species: gen. <i>Echinostoma</i> , <i>Echinocasmus</i> , <i>Acanthoparyphium</i> , <i>Artytechinostomum</i> , <i>Hypoderaeum</i>
Fasciolidae	<i>Fasciola hepatica</i> , <i>Fasciolopsis buski</i>	<i>Fasciola gigantica</i>
Gastrodiscidae	<i>Gastrodiscus hominis</i>	
Gymnophallidae		<i>Gymnophalloides seoi</i>
Heterophyidae	<i>Heterophyes heterophyes</i> , <i>H. nicens</i>	30 species: gen. <i>Heterophyes</i> , <i>Metagonimus</i> , <i>Haplorchis</i> , <i>Centrocestus</i> , <i>Apophallus</i> , <i>Cryptocotyle</i> , <i>Stictodora</i> , <i>Heterophyopsis</i> , <i>Pygidioopsis</i> , <i>Stellantchasmus</i>
Lecithodendriidae		<i>Phaneropsulus bonnei</i> , <i>P. spinicirrus</i> , <i>Prosthodendrium molenkamp</i>
Opisthorchiidae	<i>Opisthorchis sinensis</i> , <i>O. felineus</i>	<i>Metorchis albidus</i> , <i>Opisthorchis viverrini</i> , <i>Pseudoamphistomum truncatum</i>
Paragonimidae	<i>Paragonimus westermani</i>	8 species: gen. <i>Paragonimus</i>
Paramphistomidae	<i>Watsonius watsoni</i>	
Plagiorchiidae	<i>Plagiorchis elegans</i>	<i>Plagiorchis muris</i>
Schistosomatidae	<i>Schistosoma haematobium</i> , <i>S. intercalatum</i> , <i>S. japonicum</i> , <i>S. mansoni</i>	16 species: gen. <i>Schistosoma</i> , <i>Austrobilharzia</i> , <i>Trichobilharzia</i> , <i>Gigantobilharzia</i> , <i>Bilharziella</i> , <i>Orientobilharzia</i>
Troglorematidae		<i>Nanophyetus salmincola</i>

Fig. 4 Diagrammatic representation of a fluke: flattened, unsegmented, ovoid-elongate, hermaphrodite helminth, equipped to move and adhere to host surfaces by means of firm muscular structures: oral (OS) and ventral (VS) suckers. Common systems: reproductive, simple nervous and excretory, incomplete digestive. Testes (TS) converge in a vas deferens (VD), followed by the cirrus (CI); ovary (OV), receptaculum seminis (RS), vitellarium (VT), ootype (OT), uterus (UT), and genital porus (GP). Cerebral ganglion (CG) connected to longitudinal nerve cords (LN) and to transverse minor ring commissures. Ciliated flame cells (FC) and excretory bladder (EX) sited posteriorly. Mouth (MO) followed by an esophagus and a blind ending intestine (IN).

Morphological and functional characteristics

The body of these worms is 1 mm - few cm long, ovoid-elongate, unsegmented. Flukes move and adhere to inner walls of epatobiliary ducts, blood vessels, bronchial tree, or gut, mostly by means of firm muscular suckers (species specific for shape and location; usually two, oral and ventral, respectively; only sometimes three, one or none) (Fig. 4). The outer surface is covered by a syncytial cytoplasmic tegument supplied of microtriches (with or without spines) that protects the worm, preserves the body shape, allows the uptake of nutrients, and is the site of the attacks on the host's defense system. Like tapeworms, flukes are lacking coelom, respiratory and circulatory system, have a nervous system simple, arranged in the same way, and are hermaphrodites (with testes different in size and number: from 2 to more than 100, depending on the species) both self- and cross-fertilizing. The only exception is represented by species of the genus *Schistosoma*, in which firstly the dioecism appears. Instead, unlike tapeworms, flukes have a digestive system (with a mouth, surrounded by the oral sucker, followed by a gut branched and blind ending), and a simple excretory system (ciliated flame cells that carry waste metabolic products along a system of tubules, which ultimately join and open to the exterior).

The metabolism mostly depends on carbohydrates and amino acids that, per pinocytosis, pass through the many microtriches present on the outer surface of the body. High molecular weight substances, instead, are ingested.

Flukes release operculated/bearing a spine eggs containing a ciliate embryo named miracidium that leave the mammal host with feces, urine, or sputum, and develops progressively into miracidium, sporocyst, redia, cercaria, and metacercaria (Fig. 5).

Basic life cycles (Fig. 6)

Evolved as primarily permanent parasite of molluscs, all species maintain a snail in their biological cycle. The life of almost all flukes involves two or more host species (heteroxenous development): humans/other mammals in which adult worms develop and reproduce sexually, and intermediate hosts in which larval stages develop and asexually multiply. They can develop in aquatic or in terrestrial environment. In detail:

- Species having an aquatic cycle

Most flukes of medical importance develop in fresh or brackish water. Their life cycle is characterized by very high intermediate host specificity, even at geographic strain level for each species. Therefore, the free-swimming stages have many kinds of sensory receptors and reach their hosts responding to environmental stimuli, such as light, gravity, temperature, magnetic field, chemo-orientation. The host-finding strategies used are greatly different at level of dispersal from the site of origin, microhabitat of preferred host selection, host-directed orientation, host contact and invasion.

In presence of water, the miracidium escapes from the egg, actively swims, searches and infects the specific gastropod mollusc. In this host, through larval stages of sporocyst, redia (sometimes two generations), it gives origin to many cercariae (about 4,000

Fig. 5 Eggs and larval stages of flukes. (1) egg with operculum (OP) or armed with a spine (SP); (2) ciliated miracidium went out from the egg; (3) sporocyst asexually reproducing; (4) redia; (5) cercaria showing the digestive system and a sucker; (6) encysted metacercaria.

from one miracidium, more than 500,000 from one snail). Developed cercariae leave the snail and, free-swimming, within 1–3 days depending on the species, encyst on aquatic plants (Fig. 6A) or recognize and penetrate their final host (Fig. 6C), or invade a second intermediate host (Fig. 6B). Cercariae arrived on plants or in a second intermediate host (mollusc, shellfish, fish) encyst and develop into metacercariae that complete their life cycle when people/another vertebrate eat these raw or undercooked plants/animals. The ingestion of metacercariae allows the development of adult hermaphrodite worms in the final location (gut, liver, bile ducts, respiratory tree, reached more or less directly), and the following release of their eggs in the environment.

Conversely, cercariae directly penetrated in the skin of the competent final host (Fig. 6C), pass to circulatory system where will develop into dioecious adults. Female worms produce eggs provided of a spine, useful to open the way through the walls (intestinal, bladder, blood vessels), pass through tissues and reach/join feces or urine to start a new cycle in the environment. In case of accidental penetration in the human skin by cercariae parasites of other animals, their development is stopped.

- Species having a terrestrial cycle (Fig. 6D)

Fig. 6 Life cycles of digeneans pathogen for humans. Development and transmission patterns of species releasing operculated eggs (A–C) that develop only in aquatic environments, and that of species having a terrestrial cycle (D).

Few species of medical importance develop on the ground. In this case the eggs, mostly excreted by vertebrates different from humans, are swallowed by land-living snails. In this host a polyembryonic mitotic reproduction occurs involving larval stages of sporocyst, redia (sometimes two generations), and cercaria. Developed cercariae leave the snail and, ingested by the second host (ant) when eating slime balls, encyst as metacercariae. The accidental ingestion of the ant cause in the final host the development of adult worms that reach intestine or bile/pancreatic ducts, and release eggs then excreted with feces.

Infection, prevention, transmission

All infections are due to eating habits, except that due to immersion in fresh/brackish contaminated water.

Washing accurately vegetables before eating, cooking (or freezing before eating) edible fishes, molluscs, crustaceans, and keep from diving in possibly contaminated water are the measures to prevent the infection.

People affected by adult flukes are source of infection only for intermediate hosts, and people penetrated by cercariae of species that usually parasitize other animals are a dead end for the parasite. To break the parasite transmission, apart the appropriate drug taking, infected people must avoid the environmental dispersal of feces, urine, and sputum. At public level is crucial to prevent dams from providing ecological conditions to support snails, and edible aquatic animals should be controlled (or coked/frozen at personal level).

Pathogenicity and drugs

Intestinal adult flukes in general induce mucosal lesions by suckers, and possibly severe damages in case of bowel mechanical obstruction, usually treated with drugs that cause spastic paralysis of muscle cells in the parasite (as praziquantel).

On the contrary, the many systemic species induce severe damages such as obstructive, hemorrhagic, fibrotic and neoplastic type, due initially to the action of the migrating (possibly also in aberrant locations) pre-adults, and then, more severely, to crossing and often trapped eggs and their spines. Drug currently used is praziquantel, or drugs that irreversibly inhibit nucleic acid synthesis (oxamniquine, artemether), or induce starvation of the parasite (albendazole, triclabendazole), or decrease the ATP synthesis (halogenated bisphenols as bithionol).

Nemathelminthes

The phylum encloses only one class of worms of parasitic significance: that of Nematoda, commonly named roundworms due to their appearance in cross-section.

Nematodes

Many intestinal nematodes are very old (9,000–10,000 years), as they were found in prehistoric populations of the Americas, probably brought from the Old World to the Americas by the prehistoric migrants (Fornaciari and Gaeta, 2014). The oldest dating is for hookworm eggs ($7,230 \pm 80$ years old) from archaeological sites of Brazil (Ferreira et al., 1983), whereas that for *Ancylostoma duodenale* adult is 900 BC, specimen found in a Peruvian mummy (Allison et al., 1974).

The nematodes are the most abundant animal group (about 500,000 species), widespread from the chill polar regions to the scorching equatorial ones. They include, in addition to many free-living ground, marine and freshwater species, parasites of plants and animals. Animal parasites occur in vertebrates, man included, and in arthropods. A possible and simplified classification of those of medical importance is reported in Table 3, in which zoonotic species are reported separately from anthrozo/anthropo-ones.

The nematodes significant for humans may be located in the digestive system or may be found in various tissues, lymphatics, and body cavities. All are very impactful or disabling.

According to WHO soil-transmitted intestinal nematodes are among the 10 most important agents of human diseases (together filarial nematodes, schistosomes, plasmodia, amoebae, and leishmaniae), as they cause more death than anything else (except HIV/AIDS, tuberculosis, COVID). It is noteworthy the presence, among them, of opportunistic species. In low- and middle-income tropical and subtropical countries they represent a significant public health problem reinforced by poor socio-economic conditions. Moreover, nematode group encloses the pinworm, an intestinal worm as much numerous but not soil-transmitted and not as pathogenic.

Morphological and functional characteristics

The body of these cylindrical worms, bilaterally symmetrical, is 1 mm-more than 1 m long, colorless and unsegmented; the most long are filiform and are named filariae. The body is covered by an outer layer of cuticle, underlied by the hypodermis, multi-nucleate cells that forms thick lateral, ventral, and dorsal chords protruding into the body cavity (pseudocoel) and filled by muscle cells. The cuticle is thick (reach 5–10% of the diameter of the worm), and forms pseudometameric annulations. It is greatly different in the various nematode groups and during their life, due to the presence of plaques, bosses, cordons, longitudinal ridges, lateral hooklet, and cervical or caudal alae (flattened wing-like expansions of the cuticle in the oesophageal and tail regions). It provides protection from environmental agents, keeps the shape, actively uptakes nutrients, allows the movement (undulating waves) of the worm and actively transports the water and all organic substances, some drugs included. Often, an additional coat (epicuticle)

Table 3 Nematodes of medical interest, grouped as usual/possible pathogens for humans or zoonotic species, and their possible classification in families.

Family	Anthropoparasites and Anthro-Zooparasites	Zooparasites
Ancylostomatidae	<i>Ancylostoma duodenale</i> , <i>Necator americanus</i>	6 species: gen. <i>Ancylostoma</i> , <i>Uncinaria</i> , <i>Bunostomum</i>
Anisakidae		8 species: gen. <i>Anisakis</i> , <i>Pseudoterranova</i> , <i>Contracoecum</i>
Ascarididae	<i>Ascaris lumbricoides</i>	6 species: gen. <i>Toxocara</i> , <i>Parascaris</i> , <i>Toxascaris</i> , <i>Lagochilascaris</i> , <i>Baylisascaris</i>
Chabertiidae	<i>Oesophagostomum bifurcum</i> , <i>Ternidens deminutus</i>	<i>Oesophagostomum aculeatum</i> , <i>Oe. stephanostomum</i>
Diectophymatidae		<i>Diectophyma renale</i>
Dracunculidae	<i>Dracunculus medinensis</i>	
Gnathostomatidae		6 species: gen. <i>Gnathostoma</i>
Gongylonematidae		<i>Gongylonema pulchrum</i>
Metastrongylidae		<i>Parastrongylus cantonensis</i> , <i>P. costaricensis</i>
Onchocercidae	<i>Brugia timori</i> , <i>B. malayi</i> , <i>Loa loa</i> , <i>Mansonella ozzardi</i> , <i>M. perstans</i> , <i>M. streptocerca</i> , <i>Onchocerca volvulus</i> , <i>Wuchereria bancrofti</i>	9 species: gen. <i>Dirofilaria</i> , <i>Onchocerca</i>
Oxyuridae	<i>Enterobius vermicularis</i>	
Panagrolaimidae	free-living <i>Halicephalobus gingivalis</i>	
Physalopteridae	<i>Physaloptera caucasica</i>	
Rhabditidae		9 free-living species: gen. <i>Rhabditis</i> , <i>Pelodera strongyloides</i> , <i>Micronema deletrix</i> , <i>Diploscapter coronata</i> , <i>Spirocerca lupi</i>
Spiruridae		<i>Mammomonogamus laryngeus</i>
Strongyloididae	<i>Strongyloides stercoralis</i> , <i>S. fuelleborni kellyi</i> , <i>S.f. fuelleborni</i>	<i>Thelazia callipeda</i> , <i>T. californiensis</i> , <i>T. rhodesi</i>
Syngamidae		
Thelaziidae		8 species: gen. <i>Trichinella</i>
Trichinellidae		5 species: gen. <i>Trichostrongylus</i> , <i>Haemonchus</i> , <i>Marshallagia</i>
Trichostrongylidae	<i>Trichostrongylus orientalis</i> , <i>T. colubriformis</i> , <i>T. brevis</i> , <i>Ostertagia</i> spp., <i>Marshallagia</i> spp.	
Trichuridae	<i>Trichuris trichiura</i>	<i>Eucoleus aerophilus</i> , <i>Paracapillaria philippinensis</i> , <i>Calodium hepaticum</i>

envelops the outer layer of the cuticle. Sensorial buds and pits (amphids and phasmids) are present at cephalic and caudal ends, respectively.

The anterior pole may present, around the buccal cavity, papillae, cuticular hooks, teeth, cutting plates, leaf crowns or lips (Fig. 7). Papillae (occur in the oesophageal region, are spine-like or finger-like processes, usually diametrically placed, and may have sensory or supportive function) are typical of species moving in tissues, whereas the cuticular structures, which help the specimen to maintain its position and, in some cases, to draw blood as nourishment, are present in species that choose various different intestinal areas to locate. So the worms may be more or less anchored to the mucosal wall or, when provided of a very sharp cephalic end, may even be partially crept in the mucosa and directly draw nutrients, blood included. Contrary, species with lips, little useful as attachment structure, move continuously along the gut or live in the lumen pointing cephalic and caudal end to the intestinal wall.

Fig. 7 Diagrammatic representation of the anterior pole of some nematodes showing possible cephalic peculiarities. (1) Lips (LP) surrounding the mouth; (2) cuticular hooks (CH); (3) sensorial papillae (SP); (4) mouth endowed of teeth (TE) or cutting plates.

Fig. 8 Diagrammatic representation of female and male nematodes: bilaterally symmetrical, unsegmented, cylindrical, 1 mm-more than 1 m long, sometimes filiform, pseudocoelomatic, oviparous or ovoviviparous or viviparous, dioecious. Males (on the right) usually smaller than females. Common systems: digestive, excretory, nervous, reproductive (with tubular gonads blind ending on one end). Straight digestive tract: mouth followed by muscular esophagus (ME) and intestine (IN) ending with an anus (AN) in females and with a cloaca (CL) converging with the reproductive system, in males. Excretory gland (EG), with excretory porus (EP). Nerve ring (NR) from which originate nervous trunks (NT); sensorial amphids (AM) and phasmids (PH) at cephalic and caudal ends, respectively. Female specimen: ovaries (OV), each followed by a receptaculum seminis (RS) and by an uterus (UT), both converging in a vagina (VA) and vulva (VU). Male specimen: testis (TS), seminal vesicle (SV), vas deferens (VD), ejaculatory duct (ED), spiculum (SP), caudal alae (CA).

Nematodes are dioecious, sexually dimorphic, with males usually smaller than females (Fig. 8). Gonads, freely floating in the fluid that fills the pseudocoel, are tubes blind ending on one end. The female gonads usually consist of two tubes (each subdivided into ovary, oviduct, receptaculum seminis, and uterus) that join in a single vagina communicating with the exterior through the vulva. The male genital tube is subdivided in testis, seminal vesicle, vas deferens, and ejaculatory duct that opens into the rectum intestine (cloaca). Copulatory structures are the spicula (usually two needle-shaped thick cuticular elements, sometimes only one), whose protrusion is stabilized by the gubernaculum. For a better attachment with the female, male specimens may be supplied with a bursa copulatrix (cuticular expansion that envelops the vulvular region of the female), or may twist its caudal end around the female (Fig. 9).

The pseudocoel contains, along with the reproductive system, a straight digestive tract (mouth, buccal cavity, muscular esophagus sucking in nutrients, intestine, rectum) completed by a subterminal anus. A simple excretory system (glands whose function is osmoregulatory, ion regulatory and secretory rather than excretory) is present in most species, and empties its content

Fig. 9 Diagrammatic representation of the caudal end of a male specimen showing the copulatory bursa, an expansion of the caudal alae (CA) that embraces the female during copulation. It is composed of two lateral lobes (LL) and a single small dorsal lobe (DL) that are supported by elongated caudal papillae called bursal rays (BR). On the right, detail of the needle-shaped spicula (SP), copulatory chitinous organs that can be protruded to copulate.

through an anterior excretory porus. Often in the pseudocoel cells named ceolomocytes are present, regarded as phagocytes able to purify the body fluid. The nervous system is simple, being a nerve ring from which originate nervous trunk anteriorly and posteriorly directed, whereas respiratory and circulatory apparatuses are absent. Food (intestinal content, body fluids, mucus, blood, etc.) is usually taken up by means of the species-specific mouth, but filarial nematodes are able to feed also through the body wall.

Nematodes living in the digestive system are almost always oviparous, whereas those living in tissues are ovoviviparous or viviparous. The number of eggs/larvae daily released by each female is very high, because the continuity of the species only relies on the sexual reproduction of the adults. Indeed, unlike what happens in platyhelminths, larval stages do not asexually reproduce.

The ontogeny runs as metamorphosis involving four larval stages (L1, L2, L3, L4) that differ first at all as far their esophagus: muscular bulb in L1s and L2s, and capillary tube in L3s (Fig. 10); in each of them the cuticle must be shed.

Fig. 10 Diagrammatic representation of the cephalic end of nematode larval stages. L1 showing a sturdy esophagus muscular bulb shaped (MB), and L3 equipped with a long capillary esophagus (CA).

Basic life cycles (Figs. 11 and 12)

The life cycle may be direct (monoxenous development) or indirect (with vertebrates/arthropods as intermediate/vector hosts). In detail:

- Direct life cycle

It's the cycle typical of nematodes (oviparous and viviparous) located in the gut. It may be very fast, as happens in pinworms: the eggs produced are already embryonated and within few hours contain infectious L3 that, if ingested, complete their development to L4s and adults in the intestine of the new/same host (Fig. 11A). However, in most cases the cycle is less fast as females lay eggs not yet embryonated. They need oxygen to complete the embryogenesis that, therefore, will occur in the environment, on the soil, in long times (3–4 weeks) and optimal temperature and humidity. Species belonging to this group are therefore called geo-helminths, i.e., they are soil-transmitted and are the etiological agents of the most prevalent neglected tropical diseases worldwide. Embryogenesis may occur inside the eggshell or outside. In the first case (Fig. 11B) the eggs containing the developing larvae, swallowed by a new host (with vegetables, soil or, seldom, eating intermediate hosts of zoonotic species), develop into L4s and, then, in adults, in the digestive system directly or after doing a pulmonary migration. That is: hatched larvae pass through the gut wall, enter the blood stream, reach heart, pulmonary alveoli, respiratory tree, pharynx, esophagus, digestive system where develop into L4s and adult worms. This peculiar migration is considered as a phylogenetic reminiscence of a cycle in past completed in two different hosts. In other species embryogenesis occurs outside the egg since the L1s and L2s, having a muscular esophagus, may take food from the environment and free live (Fig. 11C). However they, developed into L3s, change the esophagus in a capillary tube unable to digest available nutrients and are, therefore, forced to find a host (they are the only infectious stage). Host finding is performed thanks to the presence of amphids that detects different environmental stimuli such as temperature, chemicals, touch, light, and electric potential. The L3s actively burrow into the skin (sometimes into the oral mucosa) and, as above described, through the circulatory, respiratory and finally digestive systems develop into L4s and adult worms.

Less often, intestinal females, instead of oviparous, are ovoviviparous/viviparous (Fig. 12) and deliver actively moving L1s that have three options. The first is: to be excreted and complete on the soil the development to L3s, infectious via skin (Fig. 12A) or, in case of immunosuppression, to pierce directly the intestinal wall and migrate in different tissues of the same host starting a cycle of internal autoinfections, often lethal. The second option is: to develop on the soil even till to the adult stage, free-living and here again and again reproducing (amphizoic species) (Fig. 12B). The last one is: to pierce directly the intestinal wall of the host, via blood pass through heart, lungs, heart, arrive to all cells and encyst in muscular ones of the same host, from which they may pass to a new carnivorous host that eats raw meat, and there complete the adulthood (Fig. 12C). In this case, obviously, each subject acts at the same time as final and intermediate host.

Fig. 11 Life cycles of nematodes pathogen for humans. Development and transmission patterns of oviparous species, whose biological cycle, more (A) or less (B and C) fast, takes place without intermediate hosts.

Fig. 12 Life cycles of nematodes pathogen for humans. Development and transmission patterns of viviparous species whose biological cycle takes place without (A–C) and with (D, E) intermediate hosts.

In species that perform the pulmonary migration the passage of L3s to placenta or to milk may occur, therefore further ways of transmission (mother to child) are possible, whereas in case of in tissues migrating larvae the solid organ and hemopoietic stem cells transplant transmission is possible.

- Indirect life cycle

This cycle is forced to species living, as adults, in subcutaneous/deep tissues, connective tissue, lymph nodes/ducts or body cavities. Females are viviparous and the progeny, deeply produced, needs an intermediate host to leave the host. This group of adult worms, filiform and reaching the greatest length among nematodes, is called filariae (better macrofilariae). Embryos delivered (microfilariae) move to blood and here wait for the arrival of a hematophagous insect (mosquito, horsefly, blackfly) in which they will develop into L3s. During a following blood meal of the insect on humans/vertebrate the L3s actively pass to a new final host in which reach the specific location and develop into adult worms (Fig. 12D). Finally, females of the most long filarial species, located in the subcutaneous tissue of people, with fresh water contact protrude the uterus through an ulcer-like

sore and release L1s. Microscopic crustaceans present in the water ingest the L1s and allow the development to infectious L3s that, when accidentally ingested inside the parasitized crustaceans with water, develop in man to adult worms (Fig. 12E).

Infection, prevention, transmission

Infections may be due to hygienic and socio-economic conditions, behavioral habits, direct contacts with soil, eating habits, potable water supply, or presence of insect/crustacean vector species. With regard to very few species, additional risks may be due to transmission via placenta, milk, or transplants.

Infection may be prevented by: appropriate hygienic habits; agricultural hygiene; protection of foot and hands by direct contact with contaminated soil; washing the hands before eating; washing accurately vegetables before eating; cooking (or freezing before the eating) edible meats, fishes, and crustaceans; boiling possibly contaminated water before drinking; protection by insect bites.

People affected by adult nematodes usually are source of infection for the environment or for intermediate hosts; however, they may infect themselves (in case of infection by pinworm and *Strongyloides*) and living-in (pinworm), or, rarely, the newborn (hookworms) and people recipient infected organs (*Strongyloides*). People penetrated by L3s of species that usually parasitize other animals are mostly a dead end for the parasite.

To break the parasite transmission, apart the appropriate drug taking, infected people should: make ordinary tasks accurate personal hygiene (mainly in the morning), avoid the environmental dispersal of feces and, in at risk areas, avoid insect bites and contact of the cutaneous lesions with the water. Finally, edible meats should be controlled at public level or cooked/frozen at personal level. Solid organ donors should be serologically controlled before donation, like hemopoietic stem cells that may contain infective larvae.

Pathogenicity and drugs

Intestinal adult nematodes mostly exert toxic or allergenic action, or cause severe blood loss inducing permanent intellectual and cognitive deficits from iron deficiency; moreover, they can produce severe damages in case of bowel perforation or mechanical obstruction. Opportunistic species are potentially lethal in hyperinfections. Drugs currently used cause starvation of the parasite (benzimidazoles as mebendazole and albendazole), or its immobilization/paralysis (tetrahydropyrimidine and imidathiazole groups, with drugs as pyrantel pamoate and levamisole, and macrocyclic lactones as ivermectin); they have replaced older anthelmintics as piperazine salts.

Systemic species lead to severe damages of allergenic, toxic, obstructive, and fibrotic type, sometimes heavily disabling. Migrating L3s, pre-adults, and adults of intestinal and tissue zoonotic species originate severe and difficult to be diagnosed *larva migrans* syndromes. Currently, drugs are not addressed to macrofilariae that, like pre-adult worms, may require surgical removal; however, the antibiotic therapy recently introduced and addressed to endosymbiotic *Wolbachia* bacteria present in most filarial species, proved very effective as it is indirectly macrofilaricidal and has long-term sterilizing effects. Moreover, in endemic areas the once a year administration of macrocyclic lactones as ivermectin, associated or not to diethylcarbamazine (damages the parasite tegument, reduces muscular activity and immobilizes the microfilariae), eliminate embryonic stages and circulating microfilariae for several months leading to a rapid reduction of disease transmission.

Conclusions

According to WHO, on this hearth 1/10 people suffers from 1 or more helminths, mostly associated with overcrowding, undernutrition, poor sanitation, contaminated water and food, and other poverty-related factors, worsened by conflicts that damage poor existing public health infrastructures. These parasitic infections are of concern in developing countries, however it is useful to remember that rich nations are not exempt, as demonstrated by the pinworm, which is more prevalent in the West where it represent a super-annoying problem difficult to wear out, rather increasing due to increasingly more intense social life.

Control programs had been carried out against some impacting helminths, such as schistosomes, filariae and geo-helminths, with varying degrees of success. However, it is difficult to maintain the benefits gained, as slackening of control measures and drug resistance in the parasite or its vector impends (Lustigman et al., 2017).

Therefore, despite progresses in some cases achieved, a lot rests with improvements related to socioeconomic conditions of the population at risk. Based on available general data, the sanitary problem should be faced taking into account the concrete intersection of human health, animal health, and environmental health. This implies that, beside health education and socioeconomic improvement, "any collaborative effort of multiple disciplines working locally, nationally, and globally, should be made to attain optimal health for people, animals and our environment," as defined by the One Health Initiative Task Force. An interdisciplinary approach to planetary health.

Introduction

With the term “geohelminths” and “geohelminthiases” it is usually meant several species of nematodes and associated diseases that are ecologically related although taxonomically and phylogenetically heterogeneous (Holland and Kennedy, 2002). The name comes from the Greek. γεω “soil, terrain” ἑλμινς -ινθος “worm”, thus indicating that these worms are strictly depending from soil environment for a critical developmental stage of their life cycles. Geohelminths, also known as soil transmitted helminths (STHs), belong to several orders of nematodes that are responsible of specifically human diseases as well as of zoonotic infections.

The nematodes specific to humans are mostly responsible for intestinal diseases at their adult stage while most of the zoonotic species exert their pathogenic effects through larval aberrant migrations that can be cutaneous, visceral or cerebral.

The life cycles of soil transmitted nematodes may include a free-living stage in soil where larvae undertake usually two moults to reach the third larval stage (L3), that is infective to the definitive host. The infections are therefore associated to parasitic eggs present in human feces, which may contaminate soil especially in areas where sanitation and hygienic conditions are poor. Such diseases are widespread in very low socio-economic conditions. Climatic factors can also affect the distributions of geohelminthiases, as larval development is favored by appropriate temperature and humidity. Therefore, the burden of the diseases is definitively higher in the tropical or sub-tropical regions, as sub-Saharan Africa, the Americas, China and East Asia.

Geohelminthiases represent the most widespread parasitic diseases in the world, accounting for over 1.5 billion infections (around 24% of the entire world's human population), being probably more frequent than any other infectious disease, including those from bacteria and viruses. Many mammalian-parasitic nematodes infect only one or a limited number of host species, but zoonotic transmissions and coinfections may also occur.

Despite the outstanding incidence of STHs, in particular in tropical and sub-tropical conditions, only recently efforts have been focused in limiting the impact of these diseases. Such initial scarce level of interest forced the WHO to establish a new sector called “Neglected tropical diseases” (NTDs).

General aspects of the life cycles

Despite some striking differences among species, the life cycle of geohelminths shows several shared features (also with other nematodes). All geohelminths are transmitted by eggs (or larvae) with feces of infected people or in some cases animals. All nematodes go through four moults (cuticle substitution) during larval development, shifting from the first to the fourth larval stage (L1 → L2 → L3 → L4), up to the adult stage. L1 and L2 are typically free-living stages and are known as rhabditoid (or rhabditi-form) larvae; they can survive both free in the soil or within the egg. Rhabditoid larvae are characterized by the so-called rhabditoid

esophagus, (i.e., a bulb-like esophagus, armed with robust tricuspid valves, able to grind solid substances). The other two stages L3 and L4 are always parasitic forms and are known as strongyloid (or filariform) larvae. They show a filariform thin and straight esophagus, adapted to pre-digested food intake.

In the case of *Ascaris lumbricoides* and *Trichuris trichiura*, larvae reach their infective stage still within the eggs, parasitizing the definitive hosts following their ingestion of vegetables not carefully washed or contaminated water or directly by poor hand hygiene, particularly for children.

Other mechanisms of infections are represented by the skin-penetrating nematodes such as the human hookworms *Ancylostoma duodenale* and *Necator americanus*, and the human threadworm *Strongyloides stercoralis*. They show similar life cycles inside the host, but eggs are the developmental stage that reach the environment for hookworms, while *S. stercoralis* larval form can be observed in stool as the eggs with thin walls hatches directly into the host intestine. Infective larvae commonly infect a new host through the feet skin penetration. The two kind of skin-penetrating parasitic nematodes vary in their host-seeking strategies. The dog hookworm *Ancylostoma caninum* and the human hookworms *A. duodenale* and *N. americanus* are ambushers that remain relatively motionless in the absence of stimulation, starting to crawl following the contact with the host (Haas et al., 2005). By contrast, *Strongyloides* species appear to be more motile (Gang and Hallem, 2017).

Excluding the members of the species *T. trichiura*, that reach directly the intestine where they develop to adults, all the remaining species migrate through circulatory system using the portal vein to reach the heart and then the pulmonary capillaries. The larvae grow up in size, break the capillary and fall down in the alveoli. Subsequently, larvae are coughed up reaching the glottis and swallowed, and then pass through the stomach into the intestine, where they resume development into adults. This route is mandatory for the skin penetrating nematodes as this is the only pathway to arrive to the final site of infection. The same pathway is observed for *A. lumbricoides*, with a difference: this migration is more intriguing as it arrives to the intestine following ingestion of the eggs, then the larva penetrates the intestinal barrier, reaches the circulatory system and then undertakes the hematic migration as described above. The reason for this unusual behavior is still under debate and explanation by Fülleborn in the first years of 1900 suggested the loss of one of the hosts during the course of evolution and a return to direct transmission (Anderson, 2000).

Intestinal geohelminths

Five nematode species are parasitic at their adult stage of human intestinal tract, namely *A. lumbricoides*, *T. trichiura*, *A. duodenale*, *N. americanus* and *S. stercoralis* (the latter specifically treated in a separate chapter of this Encyclopedia). Many parasitic nematode species are co-endemic and mixed infections are frequently observed in a single individual, due to similarities in the transmission routes, environmental, socio-economic conditions and geographical distribution. Such parasitic infections can cause chronic gastrointestinal diseases, anorexia, anemia, and impairment of physical and cognitive development in children.

Ascaris lumbricoides

General aspects

The large intestinal roundworms of the genus *Ascaris* belong to the order Ascaridida (Nematoda: Secernentea). This order is classified into families that occur in a broad range of vertebrate hosts world-wide, such as fishes, reptiles, birds, and mammals including humans. The human disease caused by *Ascaris* spp. is well known from the past. The first detailed morphological description is due to Edward Tyson (1683), followed by the observations of Francesco Redi (1684). However parasitic eggs have been found in ancient remains and mummies from Peru, Brazil and Egypt. As for paleoparasitological records, iguanodont coprolites dated from 100 million years ago were found positive for ascarid eggs (Poinar and Boucot, 2006). Chinese, Egyptian, Roman and Arabic writings have also recorded the infection of *A. lumbricoides*, including citation from Hippocrates in the 5th century.

A. lumbricoides belongs to the superfamily Ascaridoidea, a taxonomic rank characterized by medium-sized to large nematodes with three lips sometimes separated by interlabia, usually inhabiting the stomach and intestine of the definitive host and generally consuming food ingested by the host.

At present the genus contains several species, of which a large number is now placed in synonymy (see Crompton, 2001), but only two have been extensively investigated as they are related to humans and to economically relevant domesticated animals as pigs, namely *A. lumbricoides* Linnaeus 1758, a parasite of humans and *Ascaris suum* Goeze 1782, which infects pigs. Although mainly found in different hosts, the two species are morphologically very conservative, with little or no variation in morphological traits.

A. suum is prevalent worldwide in both intensive and extensive pig production systems (Fig. 1), having negative impact on weight gain and marketability (Skallerup et al., 2012) representing probably the most common nematode infection (Katakam et al., 2016).

A. lumbricoides infects 1.2 billion people globally and even if DALYs (disability-adjusted life years) is around 10.5 million, ascariasis is still considered a neglected tropical disease (Dold and Holland, 2011), causing approximately 60,000 deaths in humans each year. The infection is widespread worldwide and in particular in warm and humid climates, including temperate zones during warmer months and is found in association with poor personal hygiene, poor sanitation, and/or in areas where human feces are still used as fertilizer.

Fig. 1 Adult specimens of *Ascaris suum* from the intestine of a young pig.

Similarities between the two nematodes are present also in the life cycle: adult worms live in the lumen of the small intestine. When a female reaches maturity may produce around 200,000 eggs per day. Eggs measure are $65\text{--}75 \times 35\text{--}50 \mu\text{m}$ in *A. lumbricoides* and $50\text{--}70 \times 40\text{--}60 \mu\text{m}$ in *A. suum*; the outer surface is coarsely mammillated and sticky. Fertile eggs may embryonate and become infective after several days in the soil depending on environmental conditions (13–18 days at $30\text{--}33^\circ\text{C}$). They do not hatch spontaneously and are markedly resistant and long-lived. Humans and pigs become infected upon ingestion of embryonated eggs. The larvae invade the intestinal mucosa, they reach the lungs where they migrate for 5–6 days being $0.98\text{--}1.68 \text{ mm}$ in length in 6–7 days and there they further mature in order to arrive in the small intestine, ready to develop into adult worms. These can live 1–2 years. Fully embryonated eggs can remain viable in the environment for up to 5 years under favorable conditions. Eggs of both *Ascaris* spp. can hatch in the gut of several animals like mice, rats, guinea pigs, rabbits, cattle, sheep and goats, but they are unable to reach maturity in these hosts.

Given the absence of evident diagnostic morphological features, *A. lumbricoides* and *A. suum* can be considered to be cryptic/sibling species. Nadler and De Leon (2011) defined cryptic species as morphologically indistinguishable forms that show high genetic differentiation, while sibling species are defined as cryptic sister species in a phylogenetic context. Since we have no clear information on the phylogenetic relationships with other *Ascaris* species (provided that they exist), the term cryptic rather than sibling will be used hereafter for the given taxa.

A. lumbricoides and *A. suum* are considered two distinct species (Betson et al., 2014). This issue is still under debate since their validity as separated species or the existence of a single species is not only an academic exercise. Species definition has obvious influences on the epidemiology and transmission patterns of these nematodes, and in general is crucially linked to the comprehension of biodiversity and evolution (de Meeûs et al., 2003). Species delimitation has also relevance with respect to host specificity, or to the ability of the worm to survive, develop and reproduce within its favorite or accidental hosts. To date, molecular markers are used to assist a correct species identification and the combination of a nuclear and a mitochondrial marker seem to be a reliable approach. The diagnostic key based on RFLP of nuclear ribosomal ITS allows to identify the two species and their hybrid, while mitochondrial *cox1* and *nad1* are suitable for haplotype studies according to different geographical regions or hosts, in order to evaluate the amount and nature of genetic diversity of *Ascaris* spp. circulating in humans and pigs, and to explore their zoonotic potential and cross-transmission (Zhou et al., 2011; Cavallero et al., 2013). Evidences from these molecular studies suggested the presence of gene flow between the two species and their different occurrence on the base of endemicity of the human species: a large environmental contamination from both species correspond to separated transmission cycles; on the contrary, where *A. lumbricoides* is not endemic, most of the human infections are zoonotic and *A. suum* is the causative agent of ascariasis.

Pathology and clinical aspects

The adverse pathogenic effects of ascariasis is mostly due to the host response to parasitic adults, larvae and eggs in different tissues or sites. During larval migration, molecules involved in the invasion of intestinal barrier, such as peptidases, are likely to be overexpressed, causing tissue damages and cell disruption and subsequent inflammatory response. Then, during the typical migration through the circulatory system to the lungs, at pulmonary level they penetrate the alveoli and cause an allergic reaction characterized by hypersecretion of mucus, inflammation due to eosinophils and bronchial spasm, irritation and a dry cough. Rarely, it has been recovered through pleural biopsy needle (Elhadidy et al., 2017). This pulmonary phase is usually characterized by the so-called Loeffler's pneumonia. Although the infection by *A. lumbricoides* determines a shift to the Th2 immune reaction, the protective effect to allergies is uncertain. Given their large size, the severe outcomes may be due to massive infections, especially in children, and intestinal obstruction is frequently observed. These cases usually require surgical removal of parasites. *Ascaris* can also cause malabsorption, malnutrition and Vitamin A deficiency. Additionally, as these nematodes do not attach to the intestinal mucosa, they depend on continuous movements to counteract peristalsis. So that they can accidentally migrate to the pancreatic and bile ducts and provoke obstruction and jaundice or gallbladder rupture or again migrate to the appendix.

Diagnosis

Ascariasis should be suspected in patients from endemic areas, in travelers from tropical and sub-tropical regions or in farmers working with pig farming, displaying cough, fever and eosinophilia as well as abdominal pain and vomiting. Sputum can contain Charcot-Leyden crystals. Laboratory diagnosis is based on the detection of eggs in the sediment of concentrated stools (coprodiagnosis). Both fertilized and unfertilized *Ascaris* eggs may be found at the microscopical observation (Fig. 2A and B, respectively). Imaging techniques may also be used to visualize the worms in the intestine, and cholangiograms often show their presence in the biliary tract of the liver. Pulmonary stage may be diagnosed by the collection of larvae in sputum. One or few worms can be also found in stools or in children's diapers (Fig. 3).

Trichuris trichiura

General aspects

The members of the genus *Trichuris* (Order Trichinellida) are commonly known as whipworms as they are shaped as a whip. In fact, the anterior part corresponding to the structure of the esophagus consists of a narrow tube with one to three rows of large gland cells called stichocytes and the entire glandular structure is known as a stichosome. This anterior part is usually much narrower than the posterior part of the body, that is thick and containing the reproductive organs (Figs. 4 and 5).

Fig. 2 *Ascaris* fertilized (A) and unfertilized (B) egg, visualized after coprological analysis and microscope magnification. Bars indicate dimensions in micrometers.

Fig. 3 Adult specimen of female *Ascaris* found in a child's diaper.

Fig. 4 Male specimen of *Trichuris trichiura*: caudal end.

Fig. 5 Female specimen of *Trichuris trichiura*: caudal end.

Similarly to *A. lumbricoides*, *T. trichiura* has worldwide distribution, and its occurrence and incidence are directly correlated with poor sanitation and the use of human feces as fertilizer. In fact, whipworms are listed in the NTDs with the other nematodes and usually co-occur with roundworms in the same host, but with a different and peculiar gastrointestinal localization.

It displays a simple, direct life cycle. The infection starts with the ingestion with contaminated food or water of eggs containing a third-stage larva that hatch into the small intestine. Eggs are generally lemon or barrel shaped with thick-shelled with polar, plug-like structures (Fig. 6).

The larvae migrate to the intestinal caecum where they molt and mature to adult stage. They embed into the mucosa and after 3 months the females release up to 10,000 eggs per day. Eggs are generally oviposited in a not embryonated state and become infective after a period of 20–30 days into the soil (Fig. 7).

A broad range of mammalian hosts including ruminants, marsupials, rodents, and primates can be infected by whipworms. To date, around 100 species have been described and synonymized, showing a high biodiversity in the genus. Humans are commonly infected as well, mainly by the medically-relevant species *T. trichiura* and, occasionally, by zoonotic species such as *Trichuris vulpis* and *Trichuris suis*. *Trichuris* spp. usually infect a particular host or a group of related host species and parasitic species designation is often based on an integrative approach based on morphological and molecular methodologies. The parasitic species identification is usually performed using information on host-specificity and on general morphology of eggs and adults, in combination with evidences from some diagnostic nuclear and mitochondrial molecular markers. In the case of humans and other primates, whipworms are automatically identified as *T. trichiura*, but recently its taxonomic status has been largely debated.

Fig. 6 Eggs of *Trichuris trichiura*.

Fig. 7 Female specimen of *Trichuris trichiura*: detail on vagina with eggs.

Molecular studies have revealed the existence of more than one taxon able to infect humans and other primates, including captive individuals, and new species have been described thus suggesting the status of *T. trichiura* as a complex of species, counting different cryptic taxonomic units with different ability to infect one particular or several species.

Trichuris infections in humans have been described since the 18th century, but ancient paleoparasitological evidences report the recovery of *Trichuris* eggs in Korea, dating 2000 years ago as well as findings of this species in South America in pre-Columbian times. *Trichuris* eggs were also found in the intestine of a glacier mummy from the Copper Age (about 5000 years ago), known as Ötzi or the Similaun mummy, who was recovered in an astonishingly good state of preservation on the Alps at the border between Italy and Austria.

Pathology and clinical features

Trichuriasis show mild to severe clinical outcomes, mostly related to the presence of adult worms, of approximately 4 cm in length, feeding on intestinal host tissues. Diarrhea and dysentery are common symptoms. Light whipworm infections are usually asymptomatic. The pathogenic effect of trichuriasis is mainly at gastrointestinal level, as the larval stages do not migrate as other STHs larvae do. The infection site of adults is in the large intestine, mostly caecum and colon, although they may reach the appendix and the rectum. This happens usually in heavy infections, while, when a low number of worms are present, they are usually confined

to cecum and ascending colon. Re-infection occurs as a result of contact with infective stages in the environment, most frequent in areas where sanitation is poor. The consequences of infections are related to an impairment of the nutritional status of the infected people, in particular for iron and protein loss caused by parasitic blood absorption. Iron deficiency and poor nutrition caused by parasitic competition may cause in children anemia, growth retardation, and even impaired cognitive development.

In fact, the presence of whipworms causes the typical symptoms of rectal bleeding and abdominal pain because of cell destruction and activation of the host immune system, recruiting eosinophils, lymphocytes and plasma cells. At intestinal level, an increase of macrophages, TNF α and mast cell degranulation are observed, suggesting that colitis can be regarded as a sort of localized anaphylactic reaction. Long lasting infections may produce chronic effects that are similar to IBD (intestinal bowel disease) and stools of infected people may contain a mixture of mucus, water, and blood. Heavy *Trichuris* infections may result in chronic dysentery and rectum prolapse. The inflammation is mainly produced by the intestinal tissue damage caused by the intimate embedding of the long, thin anterior end of the worm in the mucosa. Rectal prolapse, one of the most serious damage due to these nematodes, seems to occur with an intussusception mechanism, i.e., when the rectum invaginates into itself.

On the other hand, the host immune response to *Trichuris* seems to be mostly characterized by the T helper (Th) 2 cells, which prevent worm survival and facilitate their expulsion. Th2 response attenuates the Th1-driven inflammatory response. This may have the effect to impair the protection versus viral and bacterial infections. Moreover, a partial protective immunity that develops with age was observed (Truscott et al., 2015). Such features imply the potential use of parasites for therapy of inflammatory diseases. In fact, intentional exposure to intact helminths or helminth-derived products have been investigated and by now, therapy with *T. suis* eggs showed no real benefit for IBD patients, suggesting a careful evaluation is needed before its use into clinical practice. Several studies described the mechanisms by which helminths manipulate the host immune system, but little consideration has been given to the actual tested helminths and in particular to their zoonotic potential. For *T. suis*, the porcine species has the ability to infect humans, too, and its use should be carefully evaluated.

Diagnosis

Trichuriasis should be suspected in patients from endemic areas. Many cases may be asymptomatic, but severe infections display abdominal pain, blood in diarrhetic feces and rectal prolapse. Stool examination following concentration reveals the presence of the characteristic oval-shaped eggs with polar plugs. Abdominal pain and general gastrointestinal symptoms are shared with other infective agents or typical of certain human diseases, a differential diagnosis should be accounted in order to correctly identify the cause of disease.

Ancylostoma duodenale* and *Necator americanus

General aspects

Important in animal and human health, these two nematodes are also known as hookworm. *Ancylostoma duodenale* (Dubini, 1843) is the so-called “Old World hookworm” and *Necator americanus* Stiles, 1902 the “New World hookworm,” distributed in all tropical and subtropical regions, in particular after the humans first long-distance movements and the late globalization. Both belonging to the Order Strongylida, called also the bursate nematodes, they differ for geographic distribution, mouth morphology, size and pathogenic impact but they both do not occur in the northern hemisphere above 52 degrees latitude as the free-living stages require temperatures in excess of 22 °C.

A large, highly cuticularized buccal capsules provided with teeth or cutting plates is a shared features used to attach themselves to the intestinal mucosa of the host. In particular, the hook-shaped anterior end observed in *Necator* accounts for the vernacular name of these species. *A. duodenale* has a mouthpart armed with sharp teeth while *N. americanus* display two plates; both of them are chitinous and adapted for sucking blood.

It is estimated that more than 900 million individuals worldwide are infected with hookworms. The transmission is favored in warm and humid climates, but is frequently reported in temperate regions, too. Direct contact with contaminated soil is a risk factor.

Contrary to what has been observed for *Ascaris* and *Trichuris*, the infection in humans initiates by the skin penetration by L3 (filariform) larvae, even if they can also infect orally and in this case they exsheath in the gut and develop directly to adulthood without a migration to the lungs (Haas et al., 2005). The first and second stages are rhabditiform and the third stage strongyliform; the tail in all three stages is conical and pointed and the infective larva retains the cuticle of the second stage. Through blood circulation, the larvae arrive to the lungs and then they follow the same route as described in *A. lumbricoides*, that is, they penetrate the pulmonary alveoli, climbing up from the bronchial tree to the pharynx, where it can be coughed up and swallowed. So, the larvae arrive in the small intestine, where they develop to adult worms. The bloodsucking mouth allows to the worms to be firmly anchored to the mucosa. Adult females are able to lay up to 20,000 thin-shelled eggs per day for *A. duodenale* and around 10,000 eggs for *N. americanus*, which are released with human feces. Eggs are generally in the four- to six-cell stage when passed in the stool of the host. In the soil, the eggs hatch a rhabditiform larva (still not infective) that moults to a filariform L3 stage, able to penetrate intact skin and to restart a new cycle. Larvae survive in moist, shaded areas with vegetation and their life span varied from 2 to 12 months, according to environmental conditions.

Pathology and clinical features

The first phase of the infection is represented by skin penetration of the filariform larva after shedding their sheaths. This may provoke a cutaneous rash and an allergic reaction. From the subcutaneous tissues, they invade lymphatic capillaries and in turn the

larger lymph channels leading to the thoracic duct; once reached the general circulation, they arrive to the heart and lungs. After larvae enter alveoli, the development to the fourth stage begins. The lung migration phase can be the cause of pneumonia, cough and sore throat, accompanied by the already mentioned Löffler syndrome along frequently with eosinophilia.

The adult worms produce gastro-intestinal symptoms including nausea and diarrhea. At intestinal level, adults start feeding on blood, causing losses that are 10-fold more severe in *Ancylostoma* infections rather than in those caused by *Necator*, resulting in a severe anemia. In fact, a long prepatent period varying from 44 to 100 days was reported in humans infected with *N. americanus*, and adults worms may live for 5–6 years. Massive chronic infections can give rise to iron-deficiency anemia and to mental and physical retardation, especially if accompanied by other nutritional depletions.

Some species infective for others mammals can be zoonotic, as *Ancylostoma braziliense* and *Ancylostoma ceylanicum* parasites of cats and dogs (and humans for *A. ceylanicum* in Asia) may be a common cause of cutaneous *larva migrans* defined “creeping eruption,” as result from the reaction to third-stage larvae migrating in the skin of humans (Fig. 8). Larval morphology is identical in the two species of medical interest, *A. duodenale* and *A. ceylanicum*, while larvae of *N. americanus* can be distinguished from that of *A. duodenale* for the prominent walls of the buccal cavity, the anterior and smaller genital primordium and the broader esophagus. Members of the genus *Necator* occur in several animals as apes, swine and, rarely, rhinoceroses, pangolins and dogs; *N. americanus* shows also the ability to infect not only humans but also other primates.

Diagnosis

Conventional stool examinations, such as formalin-ether concentration technique, is the gold-standard of diagnosing such infection, based on the detection of the eggs. The eggs are $50\text{--}80 \times 36\text{--}42$ μm in size, segmented, clearly showing 4–8 blastomeres. If the slide is left wet and unfixed, we can observe the multiplication of blastomeres, and if the stools are left in suitable conditions, larvae will hatch out of the egg.

Larvae migrans

Several species of geohelminths that are parasitic on domestic and wild animals have been recorded to accidentally infect humans, becoming responsible of zoonotic infections generally known as “larvae migrans.”

Different syndromes have been so far described, basically differentiated in visceral (VLM), ocular (OLM), cutaneous (CLM) and neuronal larvae migrans (NLM).

Visceral (VLM) and ocular (OLM) larvae migrans

In this paragraph, basic information on the etiological agents of VLM and OLM syndromes are reported; the biology of these species is available in a specific chapter. Larvae of *Toxocara* species, and specifically the dog nematode, *T. canis* and, to a much lesser extent, the *T. cati* from cats, are causative agents of visceral (VLM) and ocular (OLM) larvae migrans syndromes. The clinical outlook of toxocariasis is classified in accordance with the affected organ. VLM includes organ diseases while OLM displays limited symptoms and findings related to ophthalmological findings. Human cases by *T. cati* are rather rare, therefore hereafter we will refer only to *T. canis* infections. A third form of disease called Covert Toxocariasis (CT) has been described mainly in children with positive

Fig. 8 Cutaneous *larva migrans* due to *Ancylostoma ceylanicum*.

Toxocara serology and the combination of several clinical signs as abdominal pain, headache, behavior disturbance and cough (Zheng et al., 2020).

Cutaneous (CLM) larvae migrans

Ancylostoma spp. are responsible for the CLM infections, mainly due to parasitic species of dogs and cats that accidentally penetrate human skin. The infection is typical of warm climate regions and may be determined by *A. braziliense*, *A. ceylanicum*, *Ancylostoma caninum* and by members of the genus *Uncinaria*. The dermatitis associated with these zoonotic infections are known as “creeping eruption” or “serpiginous rash”: after the penetration, larvae cannot disseminate through the blood circulation, and remaining under the skin, their slow migration is clearly visible as a serpiginous line, depicting the route travelled by the nematode. Pruritus is often intense and scratching may provoke bacterial hyper-infections and impetigo.

Risk factors are a close contact with soil and barefoot walking on the beach in tropical areas.

Neuronal (NLM) larvae migrans

NLM larvae migrans are due to accidental infection with the ascarid *Baylisascaris procyonis*. The raccoon roundworm is increasingly recognized as a cause of often fatal NLM especially in children and of OLM in adults. Humans become infected by accidental ingestion of infective *B. procyonis* eggs from raccoon fecal areas, contaminating food consumed fresh and not properly cleaned. The infection in human is characterized by somatic tissues migration and invasion of the central nervous system. The larvae can reach a large size in the central nervous system, causing an acute fulminant eosinophilic meningoencephalitis. Usually, the prognosis is severe despite of treatment. To date, even after anthelmintic treatment, neurological damages seem unavoidable.

Conversely to other geohelminths, the life cycle of *B. procyonis* can be monoxenic but can accidentally involve intermediate hosts, such as rodents, rabbits or birds, where the larvae provoke as well the formation of eosinophilic granulomas in several tissues.

The clinical picture associated to this infection includes VLM, NLM and OLV. VLM often involves damages in heart, lungs, intestinal wall and lymph nodes, among others. NLM usually develops after 2–4 weeks after infection.

Treatment of geohelminthiases

Intestinal infections due to soil transmitted nematodes are treated using anthelmintic drugs. Among the most commonly used are benzimidazoles as albendazole and mebendazole. Albendazole is a vermicide that act in several different manners, by causing degenerative alterations in the intestine of the worm by inhibiting tubulin assemblage, depleting the glycogen stores, blocking egg production and inhibiting the Krebs cycle. Mebendazole mechanisms of action is similar to albendazole. Both drugs cause ATP depletion and nematode paralysis.

Ivermectin derives from the avermectin family of compounds and is routinely used to control parasitic worms in the gastrointestinal tract of ruminant animals worldwide. The wide and successful use of this treatment for the control of river blindness and lymphatic filariasis makes their inventors as worthy to be awarded of the Nobel Prize in Medicine in 2015. Ivermectin is a macrocyclic lactone which interfere with nervous system and muscles of the nematodes by inhibiting the neurotransmission through an alteration of ion chloride channels, thus causing the nematode paralysis as benzimidazoles.

The above compounds are routinely used not only for the specific treatment of human cases of helminthic infections, but also in massive deworming programs that have been implemented in the last decade, known as Massive Drug Administration (MDA), with the commitment of pharmaceutical companies to donating medicines specifically targeted to NTDs.

Nowadays, self-treatment for intestinal worm infection is a common public health issue, and the delivery of donated drugs through mass drug programs for soil-transmitted helminths exceeds 1 billion doses annually (Bundy et al., 2017). Specific donations are targeted at school-age children and comprise 400 million treatments of albendazole, 200 million treatments of mebendazole as well doses of ivermectin, the last intended to be used against onchocerciasis and filariasis but with an effect also on STHs.

In this context, monitor plans to detect the potential emergence of drug resistance in treated populations are mandatory. Resistance to benzimidazoles is in fact a relevant issue and it has already been observed in livestock (Morgan et al., 2019). Excluding a portion of the community from treatment is a strategy that can slow the emergence of drug resistance, although it may have an adverse effect in the success of elimination programs.

Introduction

Giardia is a one-celled protozoan that can cause diarrheal illness in humans and animals. Giardiasis is often reported in locations with low socio-economical conditions, but it can be acquired worldwide. Repeated *Giardia* infections in children can affect their growth, nutritional status, and cognitive functions. In most instances transmission is waterborne, but giardiasis can also be acquired via ingestion of contaminated foods and by exposure to infected persons or animals. Metronidazole is the most frequently used antibiotic for treatment of giardiasis, but prevention can be achieved by following good sanitary practices and avoiding ingestion of untreated water. Giardiasis has been a notifiable disease to the Centers for Disease Control and Prevention (CDC) in the U.S. since 1993. In 2018, 15,579 cases were reported. The incidence of giardiasis in the U.S. is less than seven cases per 100,000 population since 2011 (CDC, 2018).

In this article we address aspects of *Giardia* and giardiasis that will provide a better understanding of their biology, epidemiology, and control. Large strides in the molecular biology of this parasite have been made recently but will not be described here.

Biology

The first account of the description of *Giardia* occurred in 1681 when Anton van Leeuwenhoek observed his own diarrheal stool. *Giardia* is a one-celled protozoan that belongs to the Phylum Metamonada in the Order Giardiida subclass Diplozoa (Thompson and Monis, 2012). There are seven species of *Giardia* (*G. agilis* in amphibians, *G. psittaci* and *G. ardeae* in birds, *G. muris* and *G. microti* in rodents, *G. peramelis* in marsupials, and *G. duodenalis* in mammals). *Giardia duodenalis* is grouped based on its genome and host specificity and species names have been proposed. *G. duodenalis* assemblages A and B infect humans and other mammals, whereas C and D are found in canids (*G. canis*), E in hoofed animals (*G. bovis*), F in cats (*G. cati*) and G in rodents (*G. simondi*), and H in pinnipeds (Thompson and Monis, 2012).

The life cycle of *G. duodenalis* (also called *G. intestinalis* and *G. lamblia*) consists of two stages: the trophozoite and the cyst. Susceptible individuals and animals acquire the infection when water or foods containing cysts are ingested (Fig. 1). The cysts excyst in the small intestine when exposed to gastric acid and bile salts. Two trophozoites are released from each cyst, multiply by binary fission, and colonize the intestinal epithelia of the duodenum and jejunum. *Giardia duodenalis* trophozoites are pyriform in shape, measuring 12–15 µm long. They have eight flagella, a ventral adhesive disk that is used for attachment, two axonemes and two median bodies. Trophozoites feed and multiply in the lumen of the small bowel or they attach to the intestinal mucosa with a ventral sucking disk. Although there is no cell invasion, massive infections result in malabsorption by reducing the surface area for absorption of nutrients. Trophozoites also elicit metabolites that are responsible for the development of diarrhea. They are environmentally sensitive and briefly survive outside the host. Cysts are considered as the main stage of infection. As a result, infection can occur upon exposure to surfaces on which *Giardia* cysts are present or by accidental ingestion of contaminated foods.

Cyst are formed in the colon and is excreted in the feces. The cysts are ovoid, measuring 10–14 µm (wide-long). Each cyst contains four nuclei. The axonemes and median bodies are prominent (Fig. 2). Cysts are the environmentally resistant form of the parasite. They can survive at 0–8 °C for about 2 months and are often associated with waterborne outbreaks. Infections may be caused by consumption of as few as 10–100 viable *Giardia* cysts (Acheson, 2009).

Giardiasis is characterized by foul-smelling watery diarrhea, gas, abdominal pain, vomiting, nausea, steatorrhea, and dehydration. The prepatent period is usually 3 days to 3 weeks (Thompson 2008) and infection can last from a few days to several months. Although most cases can resolve quickly, in some instances prolonged giardiasis can result in weight loss, retarded growth, and delayed cognitive development.

The symptoms and oocyst shedding can vary with time and recurrent episodes of diarrhea are frequent in individuals with giardiasis (Robertson et al., 2010). Infection rates have a tendency increase in late summer and early fall (Naumova et al., 2007; Noradilah et al., 2019).

Epidemiology

Giardiasis is the most common protozoal diarrheal disease in humans worldwide (Ankarklev et al., 2010; Caccio et al., 2005; Torgerson et al., 2015). Along with *Cryptosporidium*, *Giardia* species can lead to a significant morbidity and mortality rates in low income as well as industrialized countries (Caccio et al., 2005). *Giardia* has a higher prevalence in areas where sanitation is poor and adequate water treatment facilities are lacking (Ortega and Adam, 1997). It causes an estimated 8×10^8 global cases of giardiasis per year (FAO/WHO, 2014).

Giardia duodenalis is prevalent in children in low income countries (Gilman et al., 1985; Quihui-Cota et al., 2017). This prevalence has been estimated to be 15–20% in children younger than 10 years of age (Quihui-Cota et al., 2017). A cross-sectional study done from February 2013 to September 2014 in northwest Mexico found that 23% of 173 children tested were infected with *G. intestinalis* (Caccio et al., 2005). In a seroprevalence study, 40% of Mexican children younger than 10 years of age and 70% of adults older than 25 years of age had a past or present infection (Cedillo-Rivera et al., 2009). Examinations of stools from children in Bangladesh, Zimbabwe, and Nepal showed prevalence rates of *Giardia* in approximately 20% of the children (Gilman et al., 1985; Tandukar et al., 2018). A recent study reported that almost 64% of 97 individuals infected with *Giardia* in Algeria were children 1–10 years of age (Belkessa et al., 2021). Most patients positive for giardiasis are asymptomatic while others may suffer severe abdominal pain, chronic diarrhea, and/or weight loss (Belkessa et al., 2021; Quihui-Cota et al., 2017; Tandukar et al., 2018; Thomas Iv et al., 2014).

Giardia duodenalis infections are estimated to cause 2–5% of gastrointestinal infections in industrialized countries (Ortega and Adam, 1997). According to the New Zealand Public Health Surveillance committee, more than 30 cases of giardiasis per 100,000 population occur every year in that country. In 2018, children 1–4 years of age (106.0 per 100,000) and adults 30–39 years of age (51.7 per 100,000) had the highest infection rates. Southwest England has been reported to have the highest rate of *Giardia* infections per 100,000 population in England and Wales, with 20.1 cases per 100,000 population. Infections were highest for males

45 to 49 years of age in 2017 (*Giardia* data 2008 to 2017, 2021). Waldram et al. (2017) reported that the prevalence of *Giardia* infection in Lancashire households was 30%. Highest *Giardia* infection rates were associated with households having a child under 5 years of age and/or attending a daycare facility (Waldram et al., 2017). A 3-year study in Canada found a *Giardia* sp. infection rate of 19.6 per 100,000 population. A significant seasonal variation was observed, with a peak in late summer or early fall (Laupland and Church, 2005; Rose et al., 1998). Almost 1.2 million cases of giardiasis and 3581 hospitalizations are estimated to occur annually in the U.S. (Adam et al., 2016). In 2018, there were 15,579 confirmed cases of giardiasis in the U.S. The highest incidence of giardiasis was among children (age 1–4 years) for both males and females: 10.7 and 8.1 cases per 100,000 population, respectively (CDC, 2021).

Ingestion of contaminated water and direct fecal-oral transmission are the most prevalent routes of infection. *Giardia duodenalis* is considered to be a common cause of endemic waterborne diarrheal disease. Giardiasis often infects travelers to areas of endemicity. Studies of travelers to St. Petersburg in the former Soviet Union have demonstrated giardiasis-related symptoms (Brodsky et al., 1974; Ortega and Adam, 1997). Hikers, hunters, and campers are also at risk for *Giardia* infection (Mosites et al., 2018; Ortega and Adam, 1997). For instance, during the summer of 2007, a giardiasis outbreak affected attendees at a private recreational camp in California. Two days before this outbreak began, the camp had installed a slow-sand water filtration system that was filled with sand that contained substantially elevated total coliform and turbidity levels (Karon et al., 2011). Transmission can also occur among oral-anal sexual practices.

Prevalence

Water

Depending on the year, *Giardia* spp. are often the leading cause of parasite-linked outbreaks of gastroenteritis associated with drinking and recreation waters (Atwill et al., 2012; Wolfe, 1992; Schets et al., 2004; Shields et al., 2008). Several reported outbreaks of giardiasis have been associated with these waters (Adam et al., 2016; Ligda et al., 2020; Ngowi, 2020). Among 381 reported outbreaks attributed to waterborne parasitic protozoa between 2011 and 2016, *Giardia* spp. were the etiological agent in 37% (Efstratiou et al., 2017). Contaminated water sources include unfiltered surface and household water, recreational water and rivers. *Giardia duodenalis* has been detected in river water in the U.S. (Reses et al., 2018; Rose et al., 1998; Rosenthal et al., 2017), Romania (Imre et al., 2017), Germany (Strathmann et al., 2016), and Greece (Ligda et al., 2020), among other countries.

Recreational and drinking water-related outbreaks have been linked to *Giardia* in Canada. *Giardia* cysts were found in water from 53 of 72 municipalities; 18.2% of the positive samples were from treated water (Wallis et al., 1996). Portugal has experienced *Giardia* contamination in drinking water. The source of contamination was determined to be river water (Almeida et al., 2010). A South Korean province had its first documented parasitic waterborne outbreak in 2010. The incident was linked to use of a provisional water supply (Cheun et al., 2013). Others have reported *Giardia* positive samples of water taken from recreational lakes, splash parks, pools, and ponds (Ehsan et al., 2015; Srisuphanunt et al., 2010).

Hamilton et al. (2018) reported that 77% of untreated sewage water samples and 61% of treated effluent samples were positive for *Giardia* (Hamilton et al., 2018). Other studies reported that viability of *Giardia* cysts is retained for almost 9 weeks in 4 °C water (Olson et al., 1999) and that a prolonged survival of *Giardia* cysts is consistent with low temperature (<10 °C) in various types of ecological waters (deRegnier et al., 1989). Waterborne outbreaks of giardiasis can occur throughout the entire year (Wolfe, 1992), suggesting that *Giardia* cysts are resistant to environmental degradation.

Food

Although bacteria are generally associated with foodborne disease outbreaks, many cases of gastroenteritis caused by protozoa have occurred. Raw vegetables and fruits, chicken salad, clams, and oysters have been linked to giardiasis outbreaks (Adam et al., 2016). Of 15 foodborne giardiasis outbreaks, 20% implicated vegetables while 13.3% implicated fruits. Adam et al. (2016) determined that the most common sources of infection for such outbreaks are restaurants and delicatessens (44.4%) followed by private homes (19.4%). In another study, out of 642 vegetable samples, including spinach, wild cabbage, lettuce, and others obtained from street vendors in China, 73 samples were found to be positive for *Giardia*, with a prevalence of 11.4% (Li et al., 2020). *Giardia* cysts have been found in raw vegetables and fruits in India (Utaaker et al., 2017), Spain (Amoros et al., 2010), Ghana (Duedu et al., 2014), Jordan (Ismail, 2016), the U.S. (Mintz et al., 1993; Porter et al., 1990), and other countries. Outbreaks have been linked *Giardia* infections to consumption of contaminated shellfish and clams (Manore et al., 2020; Schets et al., 2007).

Human pathogenic parasites in surface and untreated waters used for irrigation can result in contamination of food crops that are minimally processed (Mota et al., 2009; Thurston-Enriquez et al., 2002). An increase in consumption of raw fruits and vegetables can increase the risk of infection. In fact, the majority of fruit intake in the U.S. is fresh fruit and juices, and related sales accounted for about half of the total produce segment sales in 2020 (Shahbandeh, 2021). The U.S. per capita consumption of fresh vegetables was 153.32 pounds in 2019 (Shahbandeh, 2019). An increase in domestic and international trade can result in a higher exposure to produce contaminated with foodborne pathogens. Produce arrives at destination within hours or days after harvest, and agricultural practices in countries where production and harvest occur directly affect the microbial safety and health of consumers at final destination. Oysters are preferentially consumed raw, which can increase the risk of infection. Transmission may also result from cross contamination by infected, asymptomatic food handlers (Figgatt et al., 2017).

Soil

As *Giardia* is ingested, it reproduces in the host and the infective cysts are then shed in the environment, including various types of soil. Risk of soil contamination occurs when effluents such as water runoff and wastewater (Dai and Boll, 2003) carrying fecal matter are applied. Soil can consequently become a potential vehicle for *Giardia* infections. Several studies have reported the presence of *Giardia* cysts in soil (Barwick et al., 2003; Dib et al., 2008; Ferreira et al., 2018; Olson et al., 1999). Olson et al. (1999) reported that *Giardia* cysts can remain viable in soil for up to 9 weeks at 4 °C. The calculated daily risk for acquiring giardiasis is 2.3×10^{-1} when 0.02 g of soil containing *Giardia* cysts is ingested (Balderrama-Carmona et al., 2014). The risks for *Giardia* and *Cryptosporidium* infections were reported to be considerably higher in children than in adults (Balderrama-Carmona et al., 2014). Inadequate sanitary conditions such as the absence of proper water and sewage services increase the risk of soil contamination. Higher cyst concentrations are detected in soil with high moisture (Armon et al., 2002). Children and farmers who play in or work with soil, are more likely to have intestinal protozoal parasitic infections than those who do not (Shrestha et al., 2012; Tegen et al., 2020).

Soil type, pH, temperature, and plant roots, as well as water content and water flow within the soil, play a major role in the motility and survival of *Giardia*. Active motility as well as surface properties and their association with the soil particles are also considered major factors affecting survival of microorganisms in various types of soil (Mawdsley et al., 1995).

Animals

Although humans are the major reservoir for *Giardia*, several studies have shown that some animals are also capable of carrying this pathogen. Different species of *Giardia* naturally infect beavers (Dunlap and Thies, 2002; Fayer et al., 2006) and coyotes (Trout et al., 2006). Dunlap and Thies (2002) reported the presence of *Giardia* sp. in 30% of samples from beaver and 67% of samples from nutria in Texas, U.S. Samples positive for *Giardia* have also been reported in dogs (Leonhard et al., 2007; Palmer et al., 2008; Smith et al., 2020) and cats (Saleh et al., 2019; Tangtrongsup et al., 2020), as well as sheep and cattle (Godinez-Galaz et al., 2019; Santin et al., 2012). A meta-analysis study found that prevalence of *Giardia* in cattle ranges from 9% to 73% and prevalence ranges from 45% to 100% of farms (Geurden et al., 2010b). Wade et al. (2000) reported that out of 109 dairy cattle farms in the U.S., 70% were positive for *Giardia* spp. Animals with ages between 5 days through adults have been found to be positive for *Giardia* sp. cysts (Wade et al., 2000). Out of 278 fecal samples from pre-weaned dairy calves, 14.4% were positive for *G. duodenalis* (Zhong et al., 2018a). The occurrence of *G. duodenalis* in adult goats has been reported to be 14.9% (Zhong et al., 2018b). The frequency of *G. duodenalis* in cattle can lead to economic losses, as this parasite causes intermittent diarrhea and weight loss (Geurden et al., 2010a). Several *Giardia* spp. have also been found in rodents (Helmy et al., 2018; Ma et al., 2018). *Giardia duodenalis* was detected in approximately 11% of bamboo rats in China (Ma et al., 2018).

Although many farm animals and pets can be infected with the same species of *Giardia* that infect humans, these species may still differ at the molecular level (Cooper et al., 2010). It is important to detect the genotype of the species causing infection to properly determine whether farm animals actually play a role in human giardiasis. Nevertheless, the species detected in rodents by Ma et al. (2018) was later identified as assemblage B for the species also identified in human samples (Cooper et al., 2010), indicating that rodents are a potential source of zoonotic infections. Several studies have reported that animals carrying *Giardia* species are potential sources of zoonotic and anthroponotic disease (Godinez-Galaz et al., 2019; Tumova et al., 2018).

The reader interested in immunological aspects of host-*Giardia* relationship are referred to (Argüello-García et al., 2020).

Diagnosis of giardiasis

Diagnosis of giardiasis in humans and animals is done by the detection of cysts in feces. This can be accomplished by conventional coprological tests. Examination of clinical samples (stools) can be achieved by direct examination of feces using bright field microscopy. If a sample of watery diarrhea is being examined, trophozoites in motion and cysts can be clearly observed. In asymptomatic cases, cysts are more likely to be present in stool samples. Morphological features can be clearly observed if iodine is used in a wet mount. Routinely, fecal samples are collected and preserved using a fixative such as sodium acetate-acetic acid-formalin (SAF), polyvinyl alcohol (PVA), 10% buffered formalin, or merthiolate-iodine-formalin. Repeated testing may be required for an accurate diagnosis, as cyst shedding is not consistent (Hoosyar et al., 2019).

Fecal concentration methods are especially useful when a low number of cysts is being excreted. Flotation and sedimentation methods are described in most parasitology manuals. Procedures often used worldwide involve flotation in a zinc sulfate solution and sedimentation, e.g., formalin-ether sedimentation. In research laboratories, sucrose density gradients have been used to collect large numbers of cysts. *Giardia* in stool smears can also be detected with stains such as trichrome and iron hematoxylin.

A variety of commercial kits are available for detecting *Giardia*. Platforms for these kits can be based on enzyme immunoassays, rapid immunochromatographic cartridge assays, and direct fluorescent assays. Molecular assays (qPCR and PCR) are also used for examination of clinical samples (human and animal) and for research purposes. One of the latest platforms for analysis of human fecal samples is the BioFire FilmArray Gastrointestinal Panel where 22 target microorganisms (bacteria, parasites, and viruses), including *Giardia*, can be tested simultaneously (Biomerieux, Inc., Durham, NC).

Patients with symptoms consistent with giardiasis and negative parasitological results, endoscopic aspiration or the string test (entero-test) can be used to determine the presence of *Giardia* trophozoites. For the entero-test, the patient swallows a capsule

containing a nylon string of 90–140 cm. The capsule dissolves and the string is released reaching the duodenum. Four hours later or overnight the string is removed and examined for the presence of *Giardia* trophozoites. The entero-test, duodenal aspirate, intestinal biopsy and intestinal impression have been used for many years; however, they are invasive and expensive tests that don't give much benefit in diagnosis of giardiasis (Jahan et al., 2014).

Detection of *Giardia* in large volumes of drinking or irrigation water can be accomplished by filtration using filters with less than 1 μm porosity (EPA, 2012, 2014). Methods for testing water samples use filters to trap cysts and other small particles. The concentrated samples are then removed from the filters using an elution solution containing a detergent and antifoam. The eluted material is concentrated by centrifugation and the pellet is examined using immunofluorescent assays or molecular assays specific for *Giardia*.

Sanitation

Food processors use various treatments to inactivate foodborne pathogens, including *Giardia*, in food, water, and the environment. *Giardia* can survive at ambient temperature and in cold storage environments. Consequently, inactivation of *Giardia* and other parasites under these conditions is critical to public health because survival may result in sources to contaminate food. Physical, chemical, and biological treatments, alone and in combination, have been used in the food industry to inactivate *Giardia* species.

The Centers for Disease Control and Prevention (CDC) recommends boiling water for 1–3 min to kill *Giardia*. Water would then need to be stored in clean and sanitized refrigerators. In addition, cooking food will render *Giardia* cysts non-viable (Wolfe, 1992). Water, however, is consumed as an ingredient and used as a transport medium and sanitation aid (Kirby et al., 2003), which makes heat treatment inefficient for use in processing plants. Water from municipal suppliers and private wells, as well as treated wastewater and treated surface water, are various sources used in the food industry (Kirby et al., 2003). Because *Giardia* is a recognized waterborne parasite and most of the time giardiasis outbreaks are linked to its presence in water, the food industry constantly focuses on finding reliable treatment for its inactivation.

Conventional water treatment plants use coagulation, sedimentation, and filtration methods to remove *Giardia* (Swertfeger et al., 1999; Wolfe, 1992). A full-scale conventional water treatment process reduces the number of *Giardia* cysts (States et al., 1997). However, treated water can still contain low numbers of cysts so recycling of backwash water is a potential source for contamination of the treatment plant intake. A combination of physical and chemical treatments to remove *Giardia* in water sources is considered to be more efficient (Finch and Belosevic, 2001).

Chlorine based sanitizers have been used to reduce the number of *Giardia* and other microorganisms in water. A study conducted on wastewater reported that *Giardia* is inactivated when with chlorine at 0.5 mg/L for approximately 1 h (Adeyemo et al., 2019). Others have reported that along with exposure to 1.5 mg/L or higher of chlorine, temperature (25 °C) and pH (6–8) are important factors contributing to inactivation of the parasite. Statistical models for predicting survival and inactivation of *Giardia* as affected by exposure to chlorine have been developed (Haas, 2004; Haas and Heller, 1990). *Giardia* cysts are fairly resistant to treatment with chlorinated water. It is recommended that other treatments besides chlorine be used for its inactivation (Moorehead et al., 1990; Ortega and Adam, 1997).

The relative ineffectiveness of chlorine-based sanitizers for inactivation of *Giardia* cysts has led to the evaluation and adoption of alternative chemicals for water treatment. One alternative sanitizer is treatment with molecular ozone as a biocide against protozoan parasites. Ozone is a strong oxidant used in water treatment plants to enhance the removal of some naturally occurring organic and inorganic particles, algae, and other microorganisms (Can and Gurol, 2003). Treatment of surface water with 5 mg/L ozone at 23 °C and pH 7.1 inactivates 78.5% of *Giardia* cysts (Nakada et al., 2019). Kondo Nakada et al. (2020) reported that non-viable cysts of *Giardia* are more frequently detected in ozonated water (80%) than in chlorinated (68.2%) or raw water (37.7%). The reduction of calculated risk of acquiring *Giardia* infections from ozonated water is 27.5-fold and for chlorinated water is 13-fold compared to raw water (Kondo Nakada et al., 2020).

Another alternative for the removal of *Giardia* from water and wastewater is the use of ultraviolet (UV) light in treatment plants. Adeyemo et al. (2019) reported that the lethality of UV irradiation of *Giardia* cysts is higher than that of chlorine. Other studies have shown that 99.9% of *Giardia* cysts are killed by UV irradiation at 20–40 mJ/cm² (Campbell and Wallis, 2002). A UV radiation treatment of 50 mJ/cm² inactivated 75% of *Giardia* cysts (Rahdar and Daylami, 2016). *Giardia* cysts are less resistant than trophozoites to UV light treatment at 10 mJ/cm². Treatments exceeding 20 mJ/cm² prevent the excystation of *Giardia* cysts (Einarsson et al., 2015). One of the main advantages of UV treatment in water facilities is efficiency in inactivating cysts. UV treatment is a physical process that does not rely on chemicals. The formation of by-products resulting from treatment has not been reported. One limitation of the treatment is its dependence on a secure power supply, which is not always readily available in low income countries.

Other methods, including Thermophilic Windrow Composting (Van Herk et al., 2004) as well as various new technologies such as the hot bubble pilot plant (Garrido Sanchis and Jin, 2020) and the advancement of membrane technology (Betancourt and Rose, 2004), are being used to inactivate *Giardia*.

In summary, management measures are essential to improve cyst inactivation in water and wastewater, particularly when water is used in food and beverage processing and preparation. To prevent contamination, proper management and filtration systems may contribute to decreasing the infection rate and break the transmission cycle and spread of *Giardia*. Good manufacturing and agricultural practices as well as robust cleaning and disinfection of facilities and clinical settings are essential to reduce the risk of contamination and, thus, risk of infection.

Treatment and control of Giardiasis

The common antibiotic regimen for the treatment of giardiasis has been metronidazole for 7–10 days. Tinidazole, albendazole, mebendazole, and nitazoxanide have also been used to treat giardiasis. Refractory infections have been reported in various studies. A study in 95 Spanish travelers returning from Asian countries revealed that 22% had refractory giardiasis. Another similar study in Tropical Disease Units in Spain reported that 20% of infected individuals were refractory to metronidazole or tinidazole (Lalle and Hanevik, 2018).

Inactivation or removal of *Giardia* cysts from water and wastewater significantly reduce the risk of acquiring giardiasis in communities where these interventions are applied. The U.S. Environmental Protection Agency (EPA) Surface Water Treatment Rule requires that water from public water systems be filtered and that surface and well water should be treated to remove/kill 99.9% of *Giardia* present. The EPA has developed methods for detecting *Giardia* in water (1623.1 for drinking water and 1693 for wastewater) (EPA, 2012, 2014).

Common hygienic practices such as washing hands and avoidance of drinking untreated water from rivers or streams can help reduce the risk of infection. Use of adequate protective equipment in hospitals, nursing homes, hospices, and daycare centers minimizes cross contamination. Caretakers of domestic and farm animals also should take precautions to avoid cross contamination.

Development of vaccines for *Giardia* has been an important area of research in recent years. Various target proteins have been evaluated. The *Giardia* cyst wall protein 2 (CWP) and α 1-giardin are among them. The α 1-giardin is a more conserved antigen between isolates and assemblages (Radunovi et al., 2017). *Giardia* undergoes antigenic variation with about 200 surface protein variants (VSP) that results in avoidance of the host immune defenses. A vaccine using a composite of all of these VSP has been developed and tested in cats and dogs. This vaccine prevented infections and reduced chronic giardiasis in animals. When evaluated in animals of a peri-urban community in Argentina, the vaccine not only protected the vaccinated animals roaming in the area, but also was noted that the prevalence of children with *Giardia* living in this community had decreased (Serradell et al., 2016).

Conclusions

Giardia has coexisted with humans and animals since antiquity. In humans, giardiasis is frequently associated with poor socio-economical conditions (Einarsson et al., 2016). In children, repeated *Giardia* infections can result in impaired growth, nutritional status, and cognitive functions (Rogawski et al., 2017). In animals, infection can result in weight loss, poor growth, and death (Ryan and Cacciò, 2013). The zoonotic potential of giardiasis opens the possibility of acquiring the infection while practicing outdoor activities such as contact with infected animals and drinking untreated water.

Key intestinal unicellular parasites and their public health significance

A number of intestinal parasites that infect humans are multicellular, soil-transmitted helminths (*Ascaris*, *Ancylostoma/Necator*, and *Trichuris*) together with intestinal unicellular parasites (IUP), mainly protozoa, which have been included in the WHO's Neglected Diseases Initiative (Horton, 2003), cause the highest burden worldwide, requiring massive drug administration for treatment/control (Bundy et al., 2017; Horton, 2003). In this chapter, we review the current state of knowledge of the immune responses and evasion mechanisms pertaining to four major IUP and the diseases these cause in humans and other hosts, and discuss the potential of vaccines to protect against infection and transmission.

Giardia duodenalis (syn. *G. lamblia*, *G. intestinalis*) causes water- and food-borne diarrhoea in humans and a wide range of mammals. The life cycle involves vegetative trophozoites and infective cysts that following ingestion excyst and generates four trophozoites with an adhesive disk that allows its attachment to epithelial cells at duodenum and jejunum. At distal small intestine encystment proceeds and after nuclear replication mature, infective cysts are excreted in faeces and survive outside of the host for several weeks contaminating water and food. Giardiasis can be acute or chronic, and can be self-limiting. Some hosts can carry asymptomatic infections and giardiasis causes ~280 million clinical cases annually and it is more frequent in children (Kirk et al., 2015; Einarsson et al., 2016).

Entamoeba histolytica inhabits the large intestine of humans and other primates. In amebiasis that affects 500 million people worldwide a 10% of infections relate to *E. histolytica*, causing 40,000–100,000 deaths per year, and 90% to other species, particularly *E. dispar* (WHO and OMS, 1998). When the infective cyst is ingested and excysts, trophozoites can colonize without causing clinical signs (asymptomatic) or cause epithelial and mucosal ulceration (dysentery) and eventually invade intestinal tissues, reaching the portal vein causing tissue destruction and abscess formation at the liver. Amebiasis can be fatal if untreated (Ackers and Mirelman, 2006). Symptoms and signs from intestinal amebiasis can include bloody diarrhoea and fulminating dysentery, weight loss and abdominal pain whereas the extra-intestinal outcome is hallmarked by multifocal hepatic granulomata (amoebomata).

Cryptosporidium is a group of apicomplexan alveolate protists causing intestinal alterations (moderate to watery diarrhea, abdominal cramps) with or without respiratory signs. Cryptosporidiosis affects a range of animals including livestock (e.g., calves), dogs, cats, rabbits and birds. Two species cause most human infections: *C. hominis* (formerly *C. parvum* genotype 1) with human-to-human transmission and *C. parvum* with animal-to-human transmission (Ryan et al., 2016; Sow et al., 2016) causing up to >200,000 deaths per year (Guerrant et al., 1999). In its life cycle, infective oocysts in water or food are ingested and excyst in the small intestine or associated ducts, after which sporozoites are released and penetrate epithelial cells, transform briefly to trophozoites and then asexually replicate, as type I meronts, and merozoites and following maturation (type II meronts) enter a

sexual cycle, in which thin- and thick-walled oocysts of which the former re-enter in the infective cycle and the latter are released in faeces (Ryan et al., 2016). Cryptosporidiosis is endemic in developing countries of Sub-Sahara and South Asia and causes >200,000 deaths or can lead to a failure to thrive and/or impaired cognition in young children (Guerrant et al., 1999; Sow et al., 2016).

The non-flagellated, stramenophile *Blastocystis* is an emerging pathogen that infects humans, domestic (e.g., pigs) and companion (e.g., dogs) animals worldwide. Vacuolar and/or granular stages predominate in stools, amoeboid forms are rare but associated with symptomatic cases, infective cysts remain viable for 2–3 weeks outside the host and contaminate water and food. Its life cycle likely involves faecal-oral transmission and blastocystosis' symptoms include diarrhoea, abdominal pain, bloating, vomiting, nausea and/or anorexia and less frequently dermatological conditions such as urticaria, intense itching and skin redness (Stensvold et al., 2009; Verma and Delfanian, 2013). As with most intestinal protozoa, *Blastocystis* infection can be asymptomatic (Stensvold et al., 2009) and 1 billion people is likely affected worldwide (Dogruman-Al et al., 2010).

On the basis of the relatively similar life cycle but distinct pathogenic potentials displayed by these IUPs, unravelling pathological and protective immune responses is a hallmark task to design and exploit novel control strategies for the diseases they cause.

Giardia duodenalis

Giardia duodenalis is one of the major causes of protistan infections worldwide, causing giardiasis. This infection affects predominantly children in low income countries, leading to malnutrition and decreased growth/development. Giardiasis is often self-limiting, since host defence mechanisms, which include innate and adaptive immunological components, are activated upon infection. The final outcome of this infection involves the interplay between activation of immune mechanisms, the development of immunopathology and changes in the composition of the microbiota in the infected host (Fink and Singer, 2017; Barash et al., 2017). Giardiasis also constitutes a significant risk factor for post-infection irritable bowel (PI-IBS) and chronic fatigue syndromes (Chen et al., 2013; Allain et al., 2017; Hanevik et al., 2017). Advances on understanding how the innate response to *Giardia* infection is initiated and how it contributes to the development of adaptive immunity have been reviewed in detail elsewhere (Allain and Buret, 2020; Lopez-Romero et al., 2015; Roxstrom-Lindquist et al., 2006; Singer et al., 2019; Solaymani-Mohammadi and Singer, 2010). Here, a brief description of the immune mechanisms activated by this parasite is given in the next sections.

Innate immune mechanisms against *Giardia duodenalis*—Cells and effector molecules

Knowledge of the immune responses to *Giardia* have been based on in vitro investigations, in vivo studies of zoonotic *G. duodenalis* assemblages (A and B) or with *Giardia muris* in mice and gerbils and studies of cohorts of humans infected with *G. duodenalis* (Faubert, 2000). In mice, immunity to *Giardia* occurs in two major phases: a B-cell-independent phase early after infection followed by a T-cell-dependent antibody response and activation of CD8+ cells (Eckmann 2003; Muller and von Allmen, 2005). Initially, several defense mechanisms which involve innate immune cells and other molecules play a role in immunity to *Giardia*. These include intestinal epithelial cells (IECs), mucus, nitric oxide (NO) production, antimicrobial peptides, Complement, dendritic cells, mast cells and/or macrophages (Fig. 1) (Aley et al., 1994; Andersen et al., 2006; Eckmann et al., 2000; Kamda et al., 2012; Li et al., 2004, 2018; Stadelmann et al., 2013). As *Giardia* infection progresses, hosts develop mucosal humoral and cellular immune responses, which include the production of specific antibodies particularly IgA against parasite antigens, a balanced response of antigen-specific CD4+ T cells, the release of cytokines, and the activation of CD8+ cells (Fig. 1) (Faubert, 2000; Jimenez et al., 2014; Kamda et al., 2012; Roxstrom-Lindquist et al., 2006; Singer and Nash, 2000a; Zhou et al., 2007).

A first line of defense by the immune system include the natural surface barriers. In giardiasis, a major component of these are IECs, which express pattern-recognition receptors (PRRs) and initiate innate immune responses through the production of chemokines. Microarray analysis revealed that exposure of human colon carcinoma, CaCo2 cells, to *Giardia* trophozoites resulted in an increased expression of chemokines, including CXCL1-3, CCL2, and CCL20 (Roxstrom-Lindquist et al., 2005). In addition, antimicrobial peptides produced by specialised IECs have been detected, specifically the α -defensins cryptdin-2 and -3, which reduced *Giardia* viability in vitro (Aley et al., 1994) (Fig. 1A). IEC exposed to *Giardia* produce also matrix metalloprotease 7, a mediator known to activate α -defensin (Tako et al., 2013). Additionally, a brief exposure of *Giardia* to human epithelial cell cultures triggers the release of three enzymes: arginine deiminase (ADI), ornithine carbamoyltransferase and enolase which participate in host immunoregulation and metabolism in *Giardia* (Ringqvist et al., 2008). All of these studies emphasize the importance of IEC in the induction of immune responses and in the outcome of the infection.

The mucus layer protects the luminal surface of the entire gastrointestinal tract, acting as both physical and chemical barriers that *Giardia* must overcome to reach and attach to the epithelium. Some studies have suggested that intestinal mucus may interfere with trophozoite attachment and colonization (Muller and von Allmen, 2005; Roskens and Erlandsen, 2002). Although mucus protects the host from *Giardia*, it has been shown that, during the acute stage of infection, *Giardia* disrupts the triple intestinal barrier constituted by the microbiome, the mucus and the epithelial lining, which in turn initiate the pathophysiological processes ultimately responsible for disease (Allain et al., 2017) (Fig. 1B).

Recent studies in which human intestinal biopsy tissues, mouse models and human goblet cell lines were used show that the mucus barrier could be bypassed in giardiasis (Amat et al., 2017). *Giardia* cysteine proteases can cleave human mucin-2 and trigger mucus hypersecretion from goblet cells, which in turn leads to a depletion of mucin stores, both in the small and large intestines in a

Fig. 1 Immune response mechanisms against *Giardia duodenalis*. IEC cells are a first line of defense of the immune system in *Giardia* infections. These cells initiate innate immune responses through the production of chemokines. Also antimicrobial peptides like α -defensins cryptdin-2 and -3 are produced by IECs and other cells. These reduce *Giardia* viability in vitro (A and D). Mucus may interfere with trophozoite attachment and colonization but *Giardia* cysteine proteases can cleave human mucin-2 disrupting the intestinal barrier initiating the pathophysiology of giardiasis (B). NO inhibits replication and encystment of *G. duodenalis* but the parasite can inhibit the production of epithelial NO by taking up and consuming arginine as a source of energy producing ornithine that competitively inhibit arginine uptake by the intestinal epithelium blocking NO production (C). Complement can kill the parasite (E). Dendritic cells (DCs) can clear *Giardia*, present antigens to T cells and produce several cytokines and participate in the protective immune response against *Giardia* (F). Mast cells are effector cells, release pro-inflammatory cytokines such as IL-6 and degranulation of mast cell promotes peristalsis (G). Macrophages may participate in control of *Giardia* infections and present an increased expression of both nitric oxide synthase 2(NOS2) and arginase 1 (ARG1) (H). Activated T cells produce cytokines such as IL-6 that induces production of IgA which plays a role in *Giardia* clearance in rodent models of giardiasis (I). IL-17 produced by Th-17 CD4+ T cells orchestrate several immune responses that ultimately eliminate the parasite (J). Other cytokines also participate in the control of *Giardia* infections (K). In particular IL-6 participates in parasite clearance (L). Commensal intestinal microbiota participates in colonization and establishment of *Giardia* in the intestine (M), modulates pathogenesis, influences CD8+ T cell dependent-disaccharidases deficiencies (N). *Giardia* induces microbial dysbiosis (O) and secreted cathepsin proteases may aid epithelial translocation of luminal intestinal microbiota (P).

Giardia assemblage-dependent manner (Amat et al., 2017). Interestingly, a cysteine protease-dependent increase in the expression of the MUC2 gene in human goblet cells was observed due to an intracellular depletion of mucin (Amat et al., 2017). Indeed, *Giardia* cysteine proteases can cleave and activate protease-activated receptor-2 (PAR2) on intestinal goblet cells, leading to intracellular calcium release, which leads to an alteration of mucin expression and secretion (reviewed by Allain and Buret, 2020). This information suggests that goblet cell mucin production may be regulated following PAR2 activation. These alterations were associated with facilitated bacterial translocation, indicating that *G. duodenalis* evades and changes host innate defences in the mucous layer, preventing a definite immune response (Amat et al., 2017).

Gut epithelial and immune cells can synthesize NO, which has immunomodulatory and cytotoxic activities (Bogdan, 2001). Initial studies showed that NO inhibited the replication and encystment of *G. duodenalis*; however, the parasite can inhibit the production of epithelial NO by taking up and consuming arginine as a source of energy producing ornithine (Eckmann et al., 2000; Ringqvist et al., 2008) (Fig. 1C) which can competitively inhibit arginine uptake by the intestinal epithelium, thus blocking NO production (Mokrzycka et al., 2010). This block of NO production may have an effect on the proliferation of IEC (Stadelmann et al., 2012). Further, the depletion of arginine from growing CaCo2 cells decreased the number of cells when compared with medium supplemented with arginine or citrulline (Stadelmann et al., 2012), suggesting the induction of apoptosis in these cells. Interestingly, human giardiasis exhibits an increased rate of apoptosis in intestinal epithelial cells, which is a pathogenic mechanism of giardiasis (Troeger et al., 2007). A recent study has shown that host macrophages expressing arginase (Arg1) accumulate in the lamina propria of mice infected with *G. duodenalis* (Maloney et al., 2015). Thus, there is a competition for arginine during in vivo infection by at least three enzymes: ADI in the parasite, arginase (Arg1) and inducible NO synthase (NOS2) in the host.

The potential role of antimicrobial peptides in killing *Giardia* trophozoites was analyzed in vitro (Aley et al., 1994). Human neutrophil peptide (HNP-1), rabbit neutrophil peptide NP-2, bovine indolicidin, and the murine Paneth cell α -defensins, cryptdins 2 and 3, all significantly decreased trophozoite viability in vitro, whereas cryptdins 1 and 6 did not kill the parasites, suggesting a

high degree of specificity for killing trophozoites, despite the extensive sequence similarities between cryptdins (Aley et al., 1994) (Fig. 1D). Similar to its ability to inhibit production of NO, *Giardia* can protect itself from the actions of antimicrobial peptides. Studies of CaCo2 cells co-incubated with trophozoites showed increased human β -defensin 2 (HBD-2) and trefoil factor 3 (TFF3) levels compared with control cells (Manko et al., 2017). This effect could be blocked using inhibitors of cysteine proteases, suggesting that parasite proteases might be involved in this response (Manko et al., 2017). In a recent study, a dose-dependent cleavage of human β -defensin 1 (β -HD1) and α -human defensin 6 (α -HD6) was shown to be triggered by *Giardia*-released cysteine proteases in vitro (Liu et al., 2019). Due to the large numbers of antimicrobial peptides in the intestinal mucosa, further study is required to define the role of these defensins during *Giardia* infection.

The role of complement in the protective immune response against *Giardia* was initially suggested based on parasite killing induced by human sera from individuals with no history of *Giardia* infection, and this was prevented by blocking the complement pathway (Hill et al., 1984) (Fig. 1E). Studies have shown that the activation of complement takes place via both the alternative and the lectin pathways (Hill et al., 1984; Evans-Osses et al., 2010). It was shown that a mannose binding lectin (MBL) binds to trophozoites in vitro, causing lysis via the complement system (Evans-Osses et al., 2010). Other work has shown that MBL is expressed in the murine small intestine during *Giardia* infection (Tako et al., 2013) and that MBL- or complement component C3a receptor (C3aR)-deficient mice have a delayed clearance of *Giardia* and recruitment of mast cells to the small intestine (Li et al., 2016). Furthermore, more recent work showed that mice that lack C3aR have a decrease in T cell responses against *Giardia* antigens following infection, although IgA levels within the small intestine remained unaffected (Li et al., 2016). Taken together, these results demonstrate that the complement system activates immune mechanisms and mediates “downstream” immune responses during infection with *Giardia*.

Several studies have shown that DCs play a role in the clearance of *Giardia*, since IL-6-deficient mice are defective in control the parasite, and that DC are a significant source of IL-6 during infection (Bienz et al., 2003; Kamda et al., 2012; Zhou et al., 2003). On the other hand, in vitro studies have demonstrated that a modulation of DCs cytokine response can be induced by exposure of DCs to *Giardia* protein extract and lipopolysaccharide (LPS). In these studies, a reduction of IL-6, IL-12 and TNF α was observed, while IL-10 production was enhanced compared with LPS-treated control DCs (Kamda and Singer, 2009). Further, the blocking of IL-10R and phosphoinositide-3 kinase (PI-3K) restored the production of IL-12, which suggested that *Giardia* might activate PI-3K in DCs and that *Giardia* may restrict the development of Th-1 cells via IL-12 inhibition (Kamda and Singer, 2009). The reduction of pro-inflammatory cytokines was shown also in human monocyte-derived DCs (mo-DCs) stimulated with *Giardia* extracts. In these reports, a reduction in IL-12/23p40, IL-12p70, and IL-23 levels was observed (Obendorf et al., 2013; Summan et al., 2018). Moreover, a reduction in human mo-DCs survival upon exposure to *Giardia* extracts or live parasites was established, concomitant with an increase in apoptotic DCs. The results of these studies suggest that DCs participate in the protective immune response against *Giardia* (Fig. 1F).

Currently, mast cells are recognized as effector cells of the immune response against *G. duodenalis* in mast cell-deficient mice (c-kitw/wv) (Li et al., 2004, 2007). These mice failed to produce parasite-specific IgA and could not eliminate *G. duodenalis* infection, whereas wild-type mice effectively cleared the infection (Li et al., 2004, 2006, 2007). *Giardia* infections in gerbils (*Meriones unguiculatus*) and mice showed an accumulation of mast cells in the small intestine following infection where mast cell degranulation occurs (Hardin et al., 1997; Leitch et al., 1993; Venkatesan et al., 1997). Given that MBL binds to *G. duodenalis* in vitro, it has been proposed that mast cells are recruited through the activation of complement via the lectin pathway (Li et al., 2016). Other studies have shown an upregulation of protease gene transcripts in mast cells within tissues of the small intestines of mice infected with *G. duodenalis* (Tako et al., 2013).

The contribution of mast cells in resistance to reinfection with *Giardia* was further investigated in studies in which mice infected with *Giardia*, treated with metronidazole and then re-infected exhibited a rapid recruitment of mast cells to the mucosa, along with a substantially reduced intensity of infection compared with mice challenged with *Giardia* but not pre-treated with metronidazole (Li et al., 2014). Mast cells and NO may act together to induce peristalsis (Li et al., 2006, 2007) (Fig. 1G), suggesting a role of mast cells in the immunopathology of giardiasis, particularly in some patients with intestinal motility issues, such as severe cramps (Solaymani-Mohammadi and Singer, 2010). These results suggest that mast cells play a significant role in the protective immune response against *Giardia*, and in the immunopathology of giardiasis.

The role of macrophages in controlling *Giardia* infections was suggested based on the observation of an increase of intestinal macrophages in *G. muris*-infected mice. Increased expression of both NOS2 and ARG1 were recorded (Maloney et al., 2015) (Fig. 1H). Other results showed that IL-10-deficient mice infected with *G. muris* had increased cell numbers expressing CD11b+, CD11c- in the colon but not in the small intestine. Concomitant with the expansion of these cells, an inflammatory response was observed in the deficient mice infected with *G. muris* but not in wild-type mice, suggesting that these cells may regulate the inflammatory process in the infected mice (Dann et al., 2018).

Adaptive immune responses to/against *Giardia* in mammalian hosts—Role of immunoglobulin A, CD4+ and CD8+ cells, and interleukins

It has been established that antibodies contribute to the maintenance of protective immunity against giardiasis (Langford et al., 2002). The production of anti-*Giardia* antibodies has been detected in serum of and secretions from humans infected with *G. duodenalis* or mice with *G. muris* (Faubert, 2000; Nash et al., 1987; Palm et al., 2003; Tellez et al., 2005). Further, in humans with antibody-production related immunodeficiencies chronic giardiasis can develop (Eckmann, 2003; Faubert, 2000).

The main antibody involved in *Giardia* infections is IgA, a primary antibody on mucosal surfaces including those of the intestine (Fig. 1I). Anti-*Giardia* secretory IgA can be detected in human saliva and breast milk (El-Gebaly et al., 2012; Tellez et al., 2003). The role of this antibody in *Giardia*-clearance has been studied in mice infected with *G. duodenalis* or *G. muris*. Mice deficient in the production of IgA displayed a significantly delayed clearance of primary and secondary *G. muris* infections compared with control mice (Langford et al., 2002). Further, mice deficient in the poly-Ig receptor (pIgR) were shown to fail to transport secretory IgA into the intestinal lumen. Such mice develop chronic infection when inoculated orally with *G. muris*. In contrast, a lack of pIgR had no significant effect on *G. duodenalis* infection, suggesting a differential effect of secretory IgA antibodies on these two *Giardia* species (Davids, et al., 2006). Another study (Li et al., 2014), using mice with a deletion in the μ exons of the immunoglobulin heavy chain locus (μ MT mice) and lacking mature B cells, showed that when such mice were infected and re-infected with *G. duodenalis*, parasite burdens were lower soon after infection as compared with control mice that had not been primed with *G. duodenalis*, despite that these animals lack B cells. Collectively, these studies demonstrate that, although IgA-producing B cells are important for the clearance of *Giardia* infections, other immune mechanisms are activated in the infected host to counter *Giardia* infections.

Studies of humans and animals have shown that T-cell-mediated immune responses are crucial for the clearance of *Giardia* infections, since a decrease in CD4⁺ T-cell populations in both human and animals contributes to the development of chronic giardiasis (Singer and Nash, 2000a). In particular, adoptive transfer of CD4⁺ T cells to T-cell deficient mice restores their resistance to infection with *G. muris* or *G. duodenalis* (Singer and Nash, 2000a). Other studies have shown that humans infected during an outbreak of giardiasis caused by *Giardia* assemblage B had *Giardia*-reactive CD4⁺ T cells in peripheral blood, suggesting immunological memory to *Giardia* (Hanevik et al., 2011). Furthermore, the role of T cells in clearing *Giardia* was demonstrated since T-cell-deficient mice were not able to control *G. duodenalis* or *G. muris* infection, whereas B-cell-deficient mice could eliminate the parasites (Singer and Nash, 2000a).

These results suggest a B-cell-independent mechanism of CD4⁺ T cell-control during giardiasis. Interestingly, a mechanism involved in a B-cell-independent T cell activation was suggested in studies of calves infected with *G. duodenalis* that exhibited a significantly increased proliferation of CD4⁺ T cells with an increased expression of interleukin 17 (IL-17). Indeed, a central role of this cytokine in controlling infection in mice infected with *G. duodenalis* has been suggested in several studies (Solaymani-Mohammadi and Singer, 2011; Dann, et al., 2015) (Fig. 1J). Some studies of mice have reported that IL-17 is produced by splenocytes in mice early during *G. duodenalis* infection (Solaymani-Mohammadi and Singer, 2011), and IL-17 mRNA levels in the small intestine early in *G. muris* infection (Dann et al., 2015). Interestingly, other work showed that mice lacking the IL-17A receptor exhibit increased *G. muris* cyst shedding in faeces compared with wild-type mice, suggesting that IL-17A is critical for parasite elimination (Dreesen et al., 2014). IL-17A has been detected in mice infected with *G. duodenalis*, whereas IL-17A deficient mice did not clear the infection with either *G. duodenalis* or *G. muris* (Dann et al., 2015) (Fig. 1K). It has been observed that this cytokine is required for the transport of IgA into the intestinal lumen, since IL-17A deficiency led to marked reduction of faecal IgA levels, as well as an increased intestinal expression of several other potential effectors, including β -defensin 1 and resistin-like molecule β (Dann et al., 2015). These studies clearly demonstrate that IL-17 plays an important role in controlling *Giardia* infections in mice.

The role of IL-17 was also explored in humans. Study of peripheral blood mononuclear cells isolated from people with giardiasis and incubated with *G. duodenalis* extracts showed that IL-17 and TNF- α were upregulated in individuals previously exposed to *Giardia* (Saghaug et al., 2016); the accelerated elimination of *Giardia* from these individuals correlated with high levels of IL-17A and TNF- α , strongly suggesting that IL-17 has an immunoprotective role in humans against giardiasis, as it was observed in mice.

Cytokines other than IL-17 also play important roles during *Giardia* infections (Fig. 1K). Recent studies have shown that IFN- γ levels are increased in patients with symptomatic giardiasis compared with uninfected people (Babaei et al., 2016). IFN- γ and IL-4 appear to play a role because these are elevated during giardiasis in mice (Jimenez et al., 2014; Solaymani-Mohammadi and Singer, 2011). The role of IFN- γ is also supported by the results of a study in Ecuadorian children infected with the soil-transmitted helminth, *Ascaris lumbricoides*, *G. duodenalis*, or both (Weatherhead et al., 2017). In this, co-infection of children with *Ascaris* and *Giardia* induced decreased serum levels of IL-2, IL-12 and TNF- α compared with children infected with only *Giardia* (Weatherhead et al., 2017). In each group, the level of IFN- γ was not found to be reduced. Another study in a cohort of children in Venezuelan children infected with *Giardia* with a light concurrent *Ascaris* infection showed increased serum IFN- γ levels compared with children with *Ascaris*-only infection (Hagel et al., 2011).

Interleukin-6 was demonstrated to have a significant role in parasite clearance, since IL-6^{-/-} mice take a significantly longer time to clear infection compared with wild-type controls (Bienz et al., 2003; Zhou et al., 2003). Bone marrow chimera experiments have demonstrated that IL-6 from bone marrow-derived cells is necessary and sufficient for the control of *Giardia* (Kamda et al., 2012). Interestingly, dendritic cells were identified as a potent source of IL-6 (Kamda et al., 2012). Furthermore, IL-6 in combination with TGF- β , is able to drive the differentiation of naïve T cells into IL-17 producing cells (Weaver et al., 2006) suggesting that IL-6 from dendritic cells helps to drive the development of IL-17 producing CD4⁺ T cells, leading to the control of *Giardia* infection (Fig. 1L).

An increased production of IL-13 was reported in spleen cells from mice infected with either GS or WB strain *Giardia* after in vitro stimulation with parasite extracts (Solaymani-Mohammadi and Singer, 2011). Also an elevated IL-13 mRNA in mice infected with cysts of strain H3 has been reported (Bartelt et al., 2017).

In mice infected with *G. muris* mucosal IL-10 mRNA levels were shown to increase between weeks 2–4 post infection (Dann et al., 2018). IL-10 mRNA was also increased in mesenteric lymph nodes of gerbils infected with *G. duodenalis* (Serradell et al., 2018) and spleen cells from mice infected with this parasite produced IL-10 after in vitro-stimulation with parasite extracts (Solaymani-Mohammadi and Singer, 2011).

IL-8 is the key cytokine that induces inflammation during bacterial intestinal infections (Maaser and Kagnoff, 2002) and its low level during *Giardia* infection partially explains the mild inflammation. It is possible that *Giardia* can actively downregulate the inflammatory response.

It has been shown that CD8+ T cells do not play a role in controlling the infection since $\beta 2m$ -deficient mice which lack class I MHC expression and are devoid of CD8+ T cells maintain such ability. (Singer and Nash, 2000a). However, it has been reported that CD8+ T cells are required for reduction of intestinal disaccharidase activity (Scott et al., 2004) and that this is related to shortening of microvilli lining the gut (Buret et al., 1990; Scott et al., 2000) (Fig. 1N). This pathological condition has been reported in both human infections and in animal infection models and leads to reduced nutrient absorption (Buret et al., 1990, 1992).

Interactions between *Giardia* and the gut microbiota

Some recent studies have highlighted the interactions between *Giardia* and intestinal microbes (Allain et al., 2017; Fink and Singer, 2017) and suggested that a synergy occurs in a two-way mode (Allain and Buret, 2020). In this cooperative interaction, commensal microbiota appear to play a key role in the colonization and establishment of the parasite in the host (Singer and Nash, 2000b), (Fig. 1M) while the transfection of protective anti-*Giardia* microbiota into different mice prevents the establishment of the *Giardia* (Singer and Nash, 2000b), although the mechanisms involved remain to be unravelled. It has also been reported that microbiota influence the CD8+ T cell-dependent disaccharidase deficiencies observed in giardiasis (Keselman et al., 2016; Scott et al., 2004).

Other studies have shown an alteration in the composition of intestinal microbiota in acute giardiasis in mice, such as a decrease in major phyla (e.g., Firmicutes), while other minor taxa were enriched (Barash et al., 2017).

Studies have demonstrated that *Giardia* induces microbial dysbiosis in co-cultures with human mucosal microbial biofilms and increases virulence of commensal microbiota that affect human epithelial cells in vitro (Fig. 1O); these *Giardia*-altered biofilms were capable to induce immunopathology (intestinal permeability) that was dependent on microbial community disruption caused by *Giardia* secretory proteases (Beatty et al., 2017) (Fig. 1P). Further, it was suggested that these changes may be linked to symptoms present during the infection with this parasite (Allain et al., 2017; Amat, et al., 2017). Interestingly, in humans with symptomatic giardiasis an overgrowth of duodenal commensals has been observed (Chen et al., 2013; Torres et al., 2000), and it has been reported that the commensal microbiota content can modulate the pathogenesis of giardiasis (Bar et al., 2015).

All these studies indicate that intestinal microbiota impact the colonization by *Giardia* and the pathogenesis of giardiasis and likely influence the anti-*Giardia* immune response. Further considering that infections with *Giardia* may be involved into post PI-IBS and CFS, it will be interesting to understand whether disbiosis induced by *Giardia* might induce complications during or following infection.

Vaccines against *Giardia*

Up to now, several studies have been reported in relation to vaccines against *Giardia*. Of these, the *Giardia*Vax™ is the only vaccine approved against this parasite and it is only for veterinary use, specifically for canines and consists of a total lysate of trophozoites from *Giardia* isolates (Fort Dodge Animal Health, Overland Park, Kansas, United States) (Olson et al., 2000). Although it induces good IgA production and reduces the number of cysts, the induced immunity is not so efficient, therefore its use may be restricted.

Among *Giardia* proteins that have been identified as potential immunogens are the variant surface proteins (VSP) which are the dominant protein expressed on the surface of *Giardia* parasites (Prucca et al., 2011). In this context, expression of multiple surface variant proteins (VSPs) has been achieved by disrupting the RNA interference mechanism using a siRNA (Prucca et al., 2008). Thus when gerbils were infected with *Giardia* expressing multiple VSPs simultaneously they excreted fewer cysts in a secondary infection, the animals were also resistant to infection when the same *Giardia* clone was used with a single VSP, but resistance was lost when a clone with a different VSP was used (Rivero et al., 2010). When *Giardia* trophozoites expressing multiple VSPs were employed to infect dogs and cats most of the animals infected with these trophozoites were able to self-cure by day 40 post infection, whereas the animals infected with a clonal population expressing a unique VSP remained chronically infected. Importantly, most animals that were initially infected with trophozoite populations expressing the entire repertoire of VSPs were protected from future infections with clonal populations expressing a particular VSP on their surface. Furthermore, an oral vaccine formulation comprising VSPs immunopurified from trophozoites of the *Giardia* WB isolate expressing the full repertoire of their VSPs was tested in experimental infections in dogs inhabiting a *Giardia* endemic. These animals showed a reduced number of cysts that were released to the environment and, remarkably, the vaccination ceased the symptoms of the disease, suggesting that it provides protection from infection as well as parasite clearance post establishment of an infection (Serradell et al., 2016).

Further studies on immunization of gerbils with the oral vaccine comprising the entire repertoire of VSPs specifically showed high levels of IL-17, IL-6, IL-4, and IL-5, without obvious signs of inflammation. Both immunized and infected animals developed local intestinal secretory IgA and systemic (serum IgG) humoral immune responses against VSPs providing evidences on the involvement of the immune system during both symptomatic infections and protective vaccination (Serradell, et al., 2018).

Other *Giardia* antigens including $\alpha 1$ -giardin, ornithine carbamoyl transferase (OCT) and α -enolase have been tested for the induction of protection against this parasite. These proteins have been expressed using live recombinant attenuated *Salmonella enterica* serovar Typhimurium. Oral administration of the vaccine strains induced antigen specific serum IgG, particularly IgG2A, and mucosal IgA for $\alpha 1$ -giardin and α -enolase, but not for OCT. Immunization with the $\alpha 1$ -giardin vaccine induced significant

protection against subsequent *G. lamblia* challenge, which was further enhanced by boosting with cholera toxin or sublingual α 1-giardin administration. The enolase vaccine did not induce protection (Jenikova et al., 2011).

In other studies, the generation of a bivalent DNA vaccine that included CWP2 and α 1-giardin based on the attenuated strain *S. enterica* serovar Typhimurium SL7207 was reported using mice as experimental model. In these studies, it was observed that after immunization a reduction of 79% in trophozoite burden and 93% in cysts were obtained as well as an increase in IgA and IgG2 antibodies. In contrast, when CWP2 and α 1-giardin were used as univalent vaccines, a lower reduction was observed; immunization with α 1-giardin showed a 74.2% reduction in trophozoites and a 28% reduction in cysts, whereas when CWP2 was used, an 89% reduction in cysts was observed (Feng et al., 2016).

In a recent study, using a proteomic analysis, 23 *Giardia* surface antigens were identified and four of these proteins were selected. These included uridine phosphorylase-like protein-1, protein 21.1 (GL50803_2 7925), α 1-giardin, and 11-giardin. These proteins were subsequently produced in recombinant form and were administered intranasally to mice as individual purified antigens together with the prototype mucosal adjuvant cholera toxin. This immunization protocol showed that all four tested antigens reduced infection by 98% of peak parasite burden and completely prevented infection in several mice, and one antigen also shortened the infection duration; yet it is unclear how much reduction in infectious load would be required to attenuate or prevent potential clinical symptoms (Davids et al., 2019).

In the context of *Giardia* infections, vaccines should be beneficial to both animals and humans by eliminating the parasite or reducing the parasite load in the host, thus preventing shedding of cysts. This should reduce oral-fecal transmission and environmental contamination of water and food which is important in locations where giardiasis is endemic. Further, vaccination of companion and farm animals will have an impact in zoonotic transmission, thus reducing inter- and intraspecies transmission. In particular, this is important in relation to wildlife infections, where control of exposure is very difficult to achieve. Another aspect that needs to be considered is the safety of vaccines thus avoiding side effects. This together with the elimination of clinical signs or infections with *Giardia* strains that are resistant to chemotherapeutic agents should be considered in the effectiveness of a vaccine to prevent *Giardia* infections in susceptible hosts (Olson et al., 2000).

Entamoeba histolytica

Due to its great cytolytic capacity, *E. histolytica* trophozoites are considered one of the most pro-inflammatory protozoans affecting humans. Once trophozoites overcome the mucus barrier and adhere to the surface of the intestinal epithelium, an intense inflammatory response ensues, which persists throughout the invasive process. The inflammatory response is important for parasite control; however, there is also evidence that it plays a very important role in the immuno-pathogenesis of intestinal and extra intestinal amebiasis. Since *E. histolytica* trophozoites are potent inducers of inflammation, the fine-tuning of cellular infiltration levels into the tissues is extremely important in defining the outcome of infection. The main mechanisms of amoeba-induced innate and acquired immunity in intestine and liver compartments as well as their role(s) in disease control are described below.

Innate and acquired immune responses against *Entamoeba histolytica* infection

E. histolytica trophozoites relies on adhesion to the mucus layer and to the intestinal epithelium as a critical first step for colonization and establishment of infection (Fig. 2A). The mucus gel and its anti-microbial components (α -defensins, antibodies and others) constitute the first barrier of innate defense mechanisms. However, *E. histolytica* trophozoites possess potent secretagogue activity in goblet cells as a result of a signal cascade triggered by the cleavage of surface α v β 3-integrin by the parasite's cysteine protease 5 (Chadee et al., 1991; Cornick et al., 2016). The amoeba adheres to the mucus, which is generally bypassed by glycosidases and proteases from trophozoites. Once the mucus is overcome, the trophozoites interact with the intestinal epithelium through the recognition of an amoebic surface Gal-lectin adhesin by TLR2 and TLR4 in colonic cells (Fig. 2B) (Galvan-Moroyoqui et al., 2011). Canonical signaling pathways are activated, resulting in the expression of pro-inflammatory cytokines and anti-microbial peptides, such as HBD2-defensin 2 from Paneth cells (Ayala-Summano et al., 2013). A possible protective role for this peptide, as well as for peptides derived from human cathelicidin LL-37 and lactoferrin, has been suggested from in vitro studies in which membrane damage of *E. histolytica* trophozoites was observed (Lopez-Soto et al., 2010; Ayala-Summano et al., 2013; Rico-Mata et al., 2013). Moreover, high clearance rates of amoebic colitis were observed in a C3H/HeJ mouse model after oral treatment with lactoferrin and lactoferrin-derived peptides, highlighting the role of these innate molecules present in milk and in neutrophil granules (Leon-Sicairos et al., 2012; Diaz-Godinez et al., 2019).

Studies of macrophages have shown that the pro-inflammatory profile of cytokines induced by the amoebic Gal-lectin acting as PAMP via α 5 β 1-integrin is shaped by gasdermin D and caspase 1-dependent activation of the NLRP3 inflammasome and gasdermin D and caspase 1-independent activation of HMGB1 alarmin (Fig. 2B) (Mortimer et al., 2015; Quach et al., 2019; Begum et al., 2020). Amoebic calreticulin has also been shown to shape the expression of cytokine profile in peripheral blood mononuclear cells (Gonzalez Rivas et al., 2018). Among the amoeba-induced pro-inflammatory mediators, IL-8, IL-1 α , IL-1 β , IL-6, IL-12, TNF- α , IFN- γ and CXCL1 have been reported (Guo et al., 2007; Bansal et al., 2009). Once attached, the amoeba releases PGE2 which disrupts tight junctions allowing the parasite to penetrate; furthermore, the parasite induces death in the target cells by trogocytosis or apoptosis (Fig. 2C) (Lejeune et al., 2011; Ralston et al., 2014). Neutrophils are mainly recruited during the intestinal and hepatic invasion by amoeba (Fig. 2B and D). In vitro studies have shown that amoebic trophozoites activate human neutrophils, inducing

Fig. 2 Mechanisms of innate and acquired immunity during infection with *E. histolytica*. Trophozoite are exposed to microbiota, sIgA antibodies and AMPs which are degraded by parasite proteases and glucosidases (A). In the epithelium amoeba activates TLR2- and TLR4-canonical signal pathways inducing expression of pro-inflammatory cytokines. Activation of the NLRP3 inflammasome via $\alpha 5\beta 1$ -integrin also contributes to inflammation (B). Tight junctions are disrupted by trophozoite's PGE2 inducing death by trogocytosis or apoptosis, allowing the parasite to penetrate the mucosa (C). Neutrophils macrophages and eosinophils are recruited into the submucosa. Neutrophils produce ROS and release NETs and macrophages produce NO inducing protection (D). $\text{INF-}\gamma$ produced by activated neutrophils, macrophages and TCD4+ cells induce protection in intestinal amebiasis. IL-17 produced by TCD8+ cells and segmented filamentous bacteria-driven Th-17 cells, as well as IL-25, promote increase mucus secretion and immunoglobulin switching to IgA. $\text{TNF}\alpha$ and Th-2-cytokines IL-4, IL-5 and IL-13 are associated with susceptibility to intestinal amebiasis (E). Anti-amoeba secretory IgA antibodies against-Gal-lectin inhibit trophozoite adherence and protect against intestinal reinfection in children and in adults cured of ALA (F). When amoeba migrates to the liver complement, intense oxidative stress and specific IgG2a antibodies damage trophozoites. $\text{INF-}\gamma$ from iNKT cells protects the host while $\text{TNF}\alpha$ produced by macrophages induces tissue damage (G). Cytokines associated with susceptibility are in purple. Gal-lectin: Galactose/N-acetyl-galactosamine lectin; LPPG: lipopeptidophosphoglycan; PGE2: prostaglandin E2.

degranulation, ROS production and the release of pro-inflammatory cytokines and neutrophil extracellular DNA traps (NETs) (Fig. 2D) (Guerrant et al., 1981; Avila et al., 2016; Villalobos-Gomez et al., 2018). It has been reported that NETs kill *E. histolytica* trophozoites in vitro but their role in vivo is not yet known. Interestingly, trophozoites of the non-pathogenic amoeba, *E. dispar*, did not trigger NETosis, suggesting a relationship between pathogenicity and NETs formation (Fonseca et al., 2019).

The role of neutrophils in host's protection has been reported in studies in which depletion of neutrophils results in the development of larger amoebic liver abscesses (ALA) in early stages of infection in SCID mice, and in a greater percentage of intracecal infection in partially resistant (CBA strain) or susceptible (C3H/HeJ strain) mice (Seydel et al., 1997; Asgharpour et al., 2005). Nevertheless, a role for the products released by neutrophils, and by other immune innate cells, in the pathogenicity of amebiasis has been suggested (Tsutsumi and Shibayama, 2006; Pacheco-Yepes et al., 2011). For example, the inhibition of neutrophils recruitment by immunosuppression with cyclosporine A or N-acetylcysteine was shown to result in the inhibition of ALA development in hamsters even in the presence of numerous foci of aggregated amoebas (Olivos-Garcia et al., 2007).

On the other hand, macrophages, eosinophils and basophils also are recruited in amoebic infection but in lower numbers, and in vitro studies suggest that these two cell types may have a protective role in the host against this parasite. In vitro activation of $\text{INF-}\gamma$ -primed murine macrophages with a fraction of the amoebic Gal-lectin induced the release of NO that kills *E. histolytica* trophozoites (Seguin et al., 1997). In in vivo studies, macrophages and neutrophils have been associated with protection against hepatic amebiasis through the production of reactive nitrogen species (Fig. 2D) (Jarillo-Luna et al., 2002). However, protection in intestine and liver is highly dependent on the presence of $\text{INF-}\gamma$, a cytokine that activates inflammatory cells with amoebicidal activity (Fig. 2E and G). $\text{INF-}\gamma$ may be released from activated neutrophils and macrophages, but it is mainly produced early in the immune response by NKT cells, and later by TCD4+ cells. In this context, $\text{INF-}\gamma$ from TCD4+ cells have been shown to confer protection against intracaeal infection in a CBA/J mouse model, whereas $\text{INF-}\gamma$ from iNKT cells protects against ALA in a golden hamster model (Guo et al., 2009; Lotter et al., 2009; Meneses-Ruiz et al., 2015). Other cytokines related to the protection induced at the intestinal level are IL-17 and IL-25 (Fig. 2E). IL-17, produced by CD8+ T cells at the intestinal mucosa, was associated with protection against *E. histolytica* in vaccination experiments using the amoebic Gal-lectin (Guo et al., 2011a). However, a recent study

of the natural course of intestinal infection using IL-17A knockout CBA/J mice suggests that this cytokine may contribute to the persistence of the amoebic infection by modulating the ratio IFN- γ /IL-4 (Deloer et al., 2017). Detailed participation of IL-17 and IL-25 will be discussed in relation to the role of microbiota in amebiasis.

A role for mucosal eosinophils in protection (Fig. 2D) has also been recently reported in CBA/J mice following depletion of these cells using anti-Siglec-F antibodies (Noor et al., 2017). Eosinophil depletion resulted in a loss of IL-25-mediated protection and an increase in TNF- α -mediated susceptibility, a combination that resulted in an impaired gut barrier. Repletion of IL-25 in this mouse strain reversed the effects, restoring the integrity of the intestinal barrier and resistance to amoebic infection (Noor et al., 2017). In another study, eosinophilia induced by injection of a *Toxocara canis* antigen into gerbils resulted in protection against ALA, suggesting that eosinophils may also contribute to protection against extra-intestinal amebiasis (Lopez-Osuna et al., 1997). The role of basophils and mast cells has not been explored in detail, but IL-4 and IL-13 produced by these cells and by CD4⁺ T cells may be involved in disease manifestation by increasing epithelial permeability (Fig. 2E) (Houpt et al., 2002).

Interestingly, a novel mechanism of innate defense, involving STAT-3 signaling by the adipose hormone leptin, was shown to prevent amoeba-induced apoptosis of target cells (Marie et al., 2012). A 9 years follow-up study in Bangladeshi children showed a correlation between the rate of intestinal infection with *E. histolytica* and leptin suppression in malnourished children due to a leptin-receptor polymorphism (223R vs. ancestral 223Q) (Duggal et al., 2011; Guo et al., 2011b). A higher probability to develop a liver infection was also seen in adult subjects bearing the same polymorphism (Duggal et al., 2011). In general, reports based in animal models suggest that cellular-mediated innate immunity and acquired Th-1 responses may be protective against amebiasis, in contrast to a Th-2 response which is responsible for chronic infection (Fig. 2E). However, the protection observed also depends on the susceptibility of the host, since in susceptible animals (hamsters and gerbils) inflammatory cells seem to contribute to tissue damage, whereas in resistant animals (mice), inflammatory cells seem to contribute to protection by killing the parasite (Tsutsumi and Shibayama, 2006).

The acquired humoral immune response can be considered as a second line of defense in the intestinal infection by *E. histolytica*. Specific secretory IgA antibodies (sIgA) are induced when amoebic antigens released from trophozoites are presented in the Peyer's patches and the draining mesenteric lymph nodes (Fig. 2F). Anti-amoebic sIgA contained in the saliva of patients with intestinal amebiasis and in human breast milk inhibited the adherence of *E. histolytica* trophozoites to epithelial cells, preventing their destruction, and showed amoebicidal effect (Carrero et al., 1994; Leon-Sicaire et al., 2006). Evidence for the protective role of anti-amoebic sIgA antibodies in intestinal amebiasis is shown by data obtained from several field studies. Thus, a correlation between the presence of anti-Gal-lectin sIgA antibodies in stool or breast milk and reduced re-infection rates were observed in the multi-year follow-up study of the susceptible population of Bangladeshi children (Haque et al., 2001, 2006; Korpe et al., 2013). A similar association was found in patients recovered from ALA who controlled subsequent *E. histolytica* intestinal infection and developed immune memory (Ravdin et al., 2003). Moreover, in a subsequent prospective study, the clearance of *E. histolytica* and *E. dispar* infections in subjects cured from ALA correlated strongly with anti-gal-lectin sIgA peaks (Abd-Alla et al., 2006). Therefore, the stimulation of intestinal secretory response via a mucosal delivery of amoebic antigens has been proposed as a promising strategy for vaccination against human amebiasis. Once trophozoites reach the blood stream, specific IgG antibodies are produced (Fig. 2G) and can either protect or increase susceptibility to the infection, depending on the main isotype induced by the infection. A high level of anti-Gal-lectin IgG1 (Th-2 response) has been associated with active ALA and intestinal amebiasis cases, whereas anti-Gal-lectin IgG2a (Th-1 response) has been correlated with follow-up cases of ALA and asymptomatic cyst carriers (Kaur et al., 2004; Bernin et al., 2014).

Although classical and alternative pathways of human complement are activated in the presence of *E. histolytica* trophozoites causing in vitro lysis of the parasite (Calderon and Schreiber, 1985), studies on complement activation in patients with ALA or in golden hamster with ALA suggest that the complement system could be involved in the immunopathogenesis of ALA (Fig. 2D and G) (Munoz and Salazar, 1987; Olivos-Garcia et al., 2004). However, complement seems to be an important factor in the natural resistance to ALA in rats (Olivos-Garcia et al., 2018). Variations in complement susceptibility have been related to the amoeba strain used as well as with the susceptibility of the host studied.

Role of the intestinal microbiome in the immune response to amoeba

The establishment of amoebic intestinal infection has long been reported to be dependent on the presence of microbiota as germ-free animals are not colonized by *E. histolytica* trophozoites (Phillips et al., 1955; Leon-Coria et al., 2018). Thus, it has been suggested that there is bacterial-dependent expression of virulence factors in amoeba (Galvan-Moroyoqui et al., 2011). However, the interaction networks between amoeba and the microbiota are very complex and these also include microbiota-activated immune mechanisms that contribute to protection (Guo et al., 2011b).

The pioneering studies of Dr. William Petri's group on the role of microbiota in the protection against amoebic colitis have been of great importance. Initial study by this group indicated that the protection in a mouse model using the LecA fragment of Gal-lectin was dependent on the production of IL-17A, as the blockade of this cytokine abrogated the protection (Guo et al., 2011b). Since colonization of mice with the commensal *Clostridia*-related segmented filamentous bacteria (SFB) had been previously shown to promote a potent Th-17 response (Farkas et al., 2015), then they demonstrated that SFB colonization also provides protection against intestinal amebiasis (Fig. 2E and F) (Burgess et al., 2014). Moreover, protection was also obtained by adoptive transfer of bone marrow-derived dendritic cells (BMDs) from mice colonized with SFB, suggesting a cross-talk between microbiota and the bone marrow that regulates intestinal immunity and, thus, the outcome of gut infection diseases (Burgess et al., 2014). Further

studies of the effect of SBF on BMDCs showed that this protection is mediated by an increase in serum amyloid that increased the expression of Jmjd3 (a H3K27 histone demethylase), colony stimulating factor 2 receptor subunit alpha (CsF2ra) and granulocyte monocyte precursors (GMPs), promoting myelopoiesis which, in turn, increases the number of neutrophils, and probably macrophages which are recruited into the gut (Burgess et al., 2014). As a result, the innate protection against amoeba infection is activated via SFB-bone marrow cross-talk through epigenetic mechanisms.

On the other hand, the expansion of the usually commensal bacteria *Prevotella copri* in faeces of a population of Bangladeshi children was associated with diarrhoea and a high intensity of *E. histolytica* infection (Gilchrist et al., 2016), suggesting that an alteration in the microbiota could affect the course of the infection. In two recent reports, it was shown that the antibiotic-induced dysbiosis of C57BL/6 mice rendered the animals susceptible to the intracaecal infection with *E. histolytica* (Leon-Coria et al., 2018; Watanabe et al., 2017). In the first study, the susceptibility was associated with low levels of gut IL-25 and mucus protein Muc2 as well as a deficient recruitment of neutrophils to the caeca. Interestingly, a decrease in the surface expression of the chemokine receptor CXCR2 was identified in the neutrophils from mice with dysbiosis; the blockage of this receptor increased the rate of infection in control mice (Watanabe et al., 2017). In the second study, the effect of dysbiosis in the susceptibility of mice to *E. histolytica* infection was confirmed in Muc2^{+/+} and Muc2^{-/-} littermates, an effect that was only reversed in the antibiotic-treated Muc2^{+/+} mice by homologous fecal microbial transplants (Leon-Coria et al., 2018). These results highlight the link between the microbiota and the outcome of amoeba infection.

Cryptosporidium spp

As in other intestinal protozoosis, cryptosporidiosis may be asymptomatic, acute and chronic, depending largely on the host immune status or response. Immunocompetent individuals harbour parasites in the distal small intestine and may recover from acute infection within 2 weeks. However, in patients who are immunocompromised (e.g., HIV/AIDS), under immunosuppressive treatment (cancer, organ transplantation) or with inherited immunodeficiency (SCID), the infection is severe, chronic and life-threatening since it disseminates to the liver, pancreas, upper small intestine and gall bladder, thereby causing cholecystitis, cholangitis, sclerosis and pancreatitis (Cabada et al., 2015). The role of innate and adaptive immune responses in protection and development of vaccination strategies against *Cryptosporidium* spp. have been detailed elsewhere (Lemieux et al., 2018), and a brief description of immune responses to this parasite is given in the next sections.

Innate and acquired immunity in control, resolution and prophylaxis of cryptosporidiosis

Innate epithelial mechanisms activated against *C. parvum* include IECs which secrete chemokines (CXCL1, CXCL8, CXCL10, CCL2, CCL5) which attract, among others, myeloid (CD11c⁺ CD11b⁺) and double negative (CD11c⁺ CD11b⁻ CD8 α ⁻) dendritic cells (DC) in the ileum and draining lymph nodes involving IFN- γ (Auray et al., 2007) (Fig. 3A). In infected human IECs, Toll-like receptors TLR4 and TLR2 mediate MyD88, and NF- κ B signaling cascades are activated, thus leading to the secretion of free or exosome-containing antimicrobial peptides, such as LL37 and HBD2, which contribute to parasite clearance (Chen et al., 2005; Zaalouk et al., 2004) (Fig. 3B). IECs can also be induced to apoptosis, thus preventing parasite development (Laurent and Lacroix-Lamande, 2017) (Fig. 3C). Also, recruited monocytes secrete TNF α and IL-1 β , which increase the permeability and decrease integrity of epithelial barrier (de Sablet et al., 2016). Importantly, the antimicrobial effector NO (Fig. 3B) is produced independently of IFN- γ and depends on NOSII activity, as observed in *C. parvum*-infected mice and piglets. In these animal models, the inhibition of NOSII increases oocyst shedding, whereas L-arginine supplementation decreases it (Gookin et al., 2006; Leitch and He, 1994).

In relation to innate mucosal immunity, NK cells (non-T, non-B lymphocytes) act as both a source of IFN- γ , promoted by IL-12 and IL-18, and as pro-apoptotic effectors against *C. parvum*-infected IECs, releasing cytotoxic granules through an activation by IL-15. Therefore, NK cells are considered crucial contributors to the control of infection in mice (Barakat et al., 2009; Dann et al., 2005). The activation of NK requires a synergistic action of IL-18, TNF α and IL-12, the latter produced by macrophages and DC in the acute phase of infection (Bedi and Mead, 2012; McDonald et al., 2006; Urban et al., 1996). However, experiments with gene knock-down mice have shown a NK-independent mechanism, in which IL-18 along with IL-12 probably activate macrophages to produce IFN- γ because NK, T- and B-cell-deficient mice (Rag2^{-/-} γ C^{-/-}) can clear the infection (Choudhry et al., 2009). Accordingly, mice lacking IFN- γ receptor (IFN- γ R-KO) or IL-12 (IL-12KO) are highly susceptible to infection by *Cryptosporidium* spp. (Jakobi and Petry, 2008; von Oettingen et al., 2008).

Adaptive cellular immune responses are crucial for the resolution of cryptosporidiosis; indeed, individuals with defective adaptive responses have potentially fatal and long lasting courses (Hunter and Nichols, 2002). When DCs are recruited by chemokines from IECs at the early stage of the infection, they secrete IL-6 and TGF β , which induce the differentiation of intraepithelial naïve CD4⁺ T cells into regulatory Th-17 cells (Fig. 3D) which, in turn, are stimulated by IL-23 to produce IL-17. An increase of the subset of Th-17 cytokines was observed in gut-associated lymphoid tissue (GALT) and spleen of immunosuppressed, *C. parvum*-infected mice (Zhao et al., 2016). In the same infection model, IL-12 produced by macrophages and DC as well as IFN- γ produced by NK cells promote differentiation of intraepithelial naïve CD4⁺ cells into Th-1 cells (Fig. 3E). These latter cells, in turn, secrete IFN- γ , promote IgG2b production, favour conversion of naïve CD8⁺ cells into cytotoxic T cells, stimulate phagocytosis and neutrophil degranulation and release of ROS that contribute to killing intracellular *Cryptosporidium* spp. (Lantier et al., 2013; Lean et al., 2002). Despite the predominance of Th-1 cytokines, a contributory role of Th-2 cytokines as IL-4

Fig. 3 Immune response mechanisms against *Cryptosporidium* spp. During the onset of infection oocysts (Ooc) release sporozoites (Spz) that infect intestinal epithelial cells (IECs) (broken black arrows). During activation of innate immune responses, infected IECs respond by releasing cytokines for intraepithelial recruitment of monocytes (Mo) and dendritic cells (DC) (A), production of antimicrobial peptides and nitric oxide (NO) (B) as well as apoptosis induction by IL-12 activated cytotoxic natural killer (NK) cells in the presence of IFN- γ (C). At later stages of infection, adaptive immunity mechanisms include differentiation of Th-1 cells from naïve CD4+ T cells by IL-12 produced by DCs and macrophages (M ϕ) along with IFN- γ produced by NK cells (broken green lines) (D). On the other hand, DC secrete IL-6 and TGF β that promote differentiation of naïve CD4+ T cells into regulatory TH-17 cells that secrete IL-17 (E). In spite of a strong Th-1 environment, a complementary action of TH-2 cytokines as IL-4 is needed to clear parasites (F). The effector role of humoral immunity during infection or re-infection is still unclear but experimental evidence supports the protective role of sIgA in hyperimmune bovine colostrum (HBC) that blocks invasion of IECs by Spz (G). For legibility, only the infective Spz is represented attached to IECs.

is needed for *C. parvum* clearance because IL-4 accelerates resolution of infection; indeed, IL-4 displays an IFN- γ -dependent protective role (Aguirre et al., 1998; McDonald et al., 2004) (Fig. 3F). On the other hand, experiments with anti-CD4/CD8-treated mice have shown that CD4+ T cells have a predominant role over CD8+ T cells for resolving *Cryptosporidium* infection (Chen et al., 1993; McDonald et al., 1994).

The role of humoral response against *Cryptosporidium* spp. that involves systemic IgM, IgA and IgG specific antibodies (Borad et al., 2012; Kassa et al., 1991) seems neither lead to host recovery nor parasite clearance (Mead, 2014). In this context, anti-*Cryptosporidium* secretory IgA (Fig. 3G) present in AIDS patients does not protect them against cryptosporidiosis without the participation of CD4+ T cells (Cozon et al., 1994; Kassa et al., 1991). However, antibodies have a complementary role in protection, as exemplified by the prophylactic and “therapeutic” effects of hyperimmune ovine/bovine colostrum (HBC) against ovine cryptosporidiosis (Naciri et al., 1994). It is now a matter of debate as to whether anti-*Cryptosporidium* effects conferred by HBC are similar to those in humans because variable therapeutic successes were observed in HBC to HIV-immunocompromised patients (Abubakar et al., 2007; Plettenberg et al., 1993). Using immunodeficient mice models, a promising therapeutic strategy is the use of monoclonal antibodies directed against parasite antigens, such as SA-1, CSL and P23 that reduce parasite loads and oocyst shedding (Enriquez and Riggs, 1998; Perryman et al., 1993; Riggs et al., 2002). A simplified scheme depicting major mechanisms involved in innate and adaptive immune responses against *Cryptosporidium* spp. is shown in Fig. 3.

Immune evasion by *Cryptosporidium* spp

Effector mechanisms that control *Cryptosporidium* infection of IECs involve key processes, such as antimicrobial peptide production, IFN- γ signaling and apoptosis induction. The pathways that enable parasite survival and multiplication at the expense of these processes have been mainly studied in experimental rodents infected with *C. parvum*.

In the initial stages of infection, IECs produce antimicrobial peptides, such as the β -defensins mBD-1 and HBD-1, which expression is reduced by the parasite in an unknown way (Zaalouk et al., 2004). Further, CCL20 is a chemokine with anti-*Cryptosporidium* activity that is down-regulated during infection by a concomitant up-regulation of miR21 that targets CCL20 (Guesdon et al., 2015).

In the IFN- γ signalling cascade, STAT1, is an essential transcription factor that promotes the expression of multiple genes, including indolamine 2,3-dioxygenase (IDO), an enzyme that catabolizes tryptophan, an aminoacid required for *C. parvum* growth. During the infection of enterocytes, the parasite interferes with STAT1-induced IDO expression, thus restoring tryptophan pools to favour its survival (Choudhry et al., 2009).

In order to limit apoptosis of IECs, *C. parvum* has evolved some strategies. One is via the production of anti-apoptotic factors, such as BCL-2, which blocks mitochondrial cytochrome *c* release (Mele et al., 2004) as well as survivin which inhibits caspases (Liu et al., 2008). Also *C. parvum* induces the expression of osteoprotegerin, which “operates” as a decoy TNF receptor besides its ability to bind the TNF-related apoptosis-inducing ligand (TRAIL), thereby avoiding pro-apoptotic signals in IECs (Castellanos-Gonzalez et al., 2008).

Vaccines and protection against *Cryptosporidium* infection

The importance of cryptosporidiosis in the clinical and veterinary contexts, along with the complexity of *Cryptosporidium* life cycle and the multiplicity of its cell stages, impose a challenge for the development of a vaccine. Vaccination has been addressed using a variety of strategies, which include DNA-encoding proteins, subunits of defined antigens, bacterial vectors expressing parasite antigens, inactivated live parasites, and some other approaches such as antigen priming-vector boost regimes (Lemieux et al., 2018).

Initially, some DNA vaccines were designed to target selected sporozoite surface proteins of *C. parvum* (Cp), and the mechanisms leading to protective immune responses were defined in mouse models. A divalent vaccine encoding Cp12 and Cp21 displays protection (77.5% reduction of oocyst shedding by nasal route) through induction of high IgG levels and increased numbers of CD4+ and CD8 cells (Yu et al., 2010). The use of DNA encoding Cp15 and Cp23 showed a similar protection with higher IgG titers and elevated Th-1 cytokines (Wang et al., 2010). Using the sporozoite surface protein Cp15/60, mice were protected against an inoculum of up to 1×10^6 *C. parvum* oocysts (He et al., 2004). In pregnant cows, immunization with subunit vaccines using immunodominant proteins has been carried out and the corresponding HBC have been evaluated to induce protection in calves. Of these, anti-P23 HBC was reported to induce protection or at least limited symptoms and oocyst shedding (Askari et al., 2016; Perryman et al., 1999). In mice, a Cp15-Cp23 vaccine induces greater CD4+ and comparable CD8+ numbers concomitant with a significant Th-1 and antibody responses, leading to partial protection as compared with crude extracts and monovalent Cp23 vaccines (Liu et al., 2010).

In the case of live-attenuated vaccines, these may induce a long lasting, strong Th-1 and protective cell-mediated immunity, as has been shown against some bacteria, viruses and protistan pathogens (Bhattacharya et al., 2015; Buxton et al., 1993; Jenkins et al., 1997). Limited vaccination trials have been carried out, but some protection in calves has been achieved after 3 weeks of challenge using *C. parvum* oocysts inactivated by γ -irradiation at 400-Gy (Jenkins et al., 2004).

Vaccines based on attenuated viruses, bacteria or parasites carrying *Cryptosporidium* antigens have been designed for intestinal delivery to microfold cells to allow their processing in Peyer patches to stimulate mucosal immune responses (revised by Lemieux et al., 2018). In particular, live bacterial vectors such as attenuated *Salmonella enterica*, have been reported (Benitez et al., 2009; Manque et al., 2011; Roche et al., 2013). This strategy mainly involves the fusion of the parasite protein to a signal peptide (for type III secretion) and a chaperone-binding domain, providing a low-cost and readily administrable vaccine (Hegazy et al., 2012). Initial trials using attenuated *S. enterica* serovar Typhimurium SL3261 as the delivery system employing a vector (pTECH1) expressing *C. parvum* Cp23 or Cp40 fused to fragment C of the tetanus toxin under the control of the anaerobic *nir* promoter were tested for oral immunization of mice. Serum anti-Cp23 and -Cp40 IgG titers were detected after 35 days, with serum and faecal IgA being detected in 30% of Cp23-immunized mice (Benitez et al., 2009). Using reverse vaccinology, the strain *S. enterica* serovar Typhi CVD-908-*htrA*, expressing either *C. hominis* apyrase, profilin or Cp15 fused to cytolysin A and administered as heterologous prime boost regime in mice, induced strong humoral (IgG1 and IgG2b) and cellular (IFN- γ , IL-2, IL-6 and IL-12) immune responses (Manque et al., 2011). Further experiments with the same vaccine strain, but expressing the Cp15 protein by intranasal administration, in spite of inducing strong secretion of IL-6 and IFN- γ and robust anti-Cp15 IgG titers, after oral challenge with *C. parvum* oocysts, achieved only a transient reduction in oocyst-shedding without protection against disease (Roche et al., 2013). Interestingly, these studies have shown that the “Prime-Pull” vaccine approach, in which the oral dose of *Salmonella* spp. vector (“boost”) following subcutaneous immunization with Cp23 or Cp40 DNA as “prime” (Benitez et al., 2009) or *vice versa* [i.e., priming with *Salmonella* spp. vector then boosting with intraperitoneal administration of recombinant proteins (Manque et al., 2011; Roche et al., 2013)] enhances immune responses against individual immunogens.

Other studies have analyzed the *C. parvum* P23 antigen as an immunogen expressed by *Toxoplasma gondii* and the probiotic bacteria *Lactobacillus casei* in mice. Using the first vector, high titers of neutralizing IgG1, a typical subtype of Th-2 response, were achieved (Shirafuji et al., 2005), whereas the use of the latter vector induced increased levels of serum IgG, faecal IgA, IL-6 and IFN- γ (Geriletu et al., 2011), although their protective effects against *C. parvum* challenge were not further evaluated.

In a general view, protective responses against *Cryptosporidium* spp. involve specific mucosal responses in a context of a predominant Th-1 cellular immunity, supported by a Th-2 humoral response. Some vaccine candidates, such as Cp12, Cp15, Cp21, Cp40 and P23, display epitopes that need to be evaluated in analyses employing combined vaccine approaches, such as those involving systemic priming and mucosal boosting, for which ongoing work might pave the way to an effective vaccine.

Blastocystis spp

The involvement of host immune responses in the acquisition, development and outcome of *Blastocystis* infection was suggested based on the observation of the higher susceptibility of HIV(+) or cancer patients, children and tourists to this infection (Kurniawan et al., 2009; Tasova et al., 2000). In addition, spontaneous remission of the infection (22%) has been observed in population cohorts shedding *Blastocystis* in stools (van Hellemond et al., 2013). Likewise, an epidemiological link between *Blastocystis* and IBS and inflammatory bowel disease (IBD) has been reportedly seen in patients (Jimenez-Gonzalez et al., 2012; Kaser et al., 2010; Yakooob et al., 2010). However the symptomatology caused by *Blastocystis* is still contentious; hence, this may be considered as the result of interactions among parasite, host immune response and possibly microbiota-related factors, as discussed in the following sections.

Subtypes, pathogenicity, immune response and immunomodulation

This microorganism was historically referred as *Blastocystis hominis* when isolated from humans, but humans can be infected with other species (e.g., *B. ratti*). Molecular studies using the small subunit ribosomal RNA gene (SSU) revealed at least 17 *Blastocystis* subtypes (STs), all of which are morphologically similar but genetically distinct (Alfellani et al., 2013; Stensvold et al., 2007). Thereafter, the designation "*Blastocystis* spp. STnn" covers all subtypes, of which ST1 to ST9 and ST12 have been detected in humans, and ST1 to ST4 are involved in 90% of human cases (Stensvold and Clark, 2016). Further, subtypes ST18 to ST26 have been proposed to infect humans, but this finding is still controversial (Maloney et al., 2019; Stensvold and Clark, 2020).

To date, there is no proven relationship between *Blastocystis* STs and virulence, although there appears to be an association. However, key processes involved in intestinal pathogenicity have been identified. In vitro interaction experiments have shown that *Blastocystis* is able to (a) attach intestinal mucin; (b) promote tight junction alteration mediated by Rho/ROCK, which, in turn, disrupts epithelial barrier function, hence increasing permeability; (c) NF- κ B-mediated secretion of pro-inflammatory cytokines (GM-CSF, IL-1 β , IL-6, IL-8 and TNF- α) (Fig. 4A); and (d) enterocyte apoptosis by contact-independent, caspase 3-dependent

Fig. 4 Immune response mechanisms against infection by *Blastocystis* spp. and immunopathological patterns. The infective *Blastocystis* cyst (C) releases pathogenic forms that develops into vacuolar (V), ameboid or granular forms that attach to mucin and/or surface of intestinal epithelial cells (IECs). These latter activate NF- κ B signaling to produce chemoattracting chemokines for proinflammatory cells as neutrophils (Neu), polymorphonuclear cells (PMNs) and macrophages (M ϕ) (A) as well as proinflammatory cytokines (B). Two important antiparasitic effectors are nitric oxide (NO) produced from iNOS activity (C) and secretory IgA (sIgA) as predominant isotype at luminal compartment (D). *Blastocystis* counteracts some of these mechanisms by secreting proteases of the cysteine (CPs), aspartic (APs) and serine (SPs) types: CPs and APs elicit ruptures of intercellular junctions through the Rho/ROCK pathway, degrade secretory antibodies and induce contact-independent, caspase-3 dependent apoptosis in IECs (E); on the other hand SPs at the mucosal level induce production of proinflammatory cytokines from resident or recruited M ϕ . In patients with inflammatory bowel disease, particularly IBS, a decrease of T lymphocytes (CD3+) and an imbalanced proportion of CD4+ and CD8+ cells is present (F: increased, $\downarrow$: decreased) (F). Interestingly an increased production of inflammatory cytokines (IL-8, IL-12 and TNF- α) (G) and even single nucleotide polymorphisms (SNPs) in sequences of cytokines as IL-8 and IL-10 (H) have been associated to these inflammatory outcomes.

mechanisms (Lim et al., 2014; Puthia et al., 2006) (Fig. 4B). The high genetic variability among *Blastocystis* isolates is a major contributing factor, not only to explain the distinct inter-ST and intra-ST abilities to induce the alterations mentioned above (Gentekaki et al., 2017; Wu et al., 2014), but also to define likely virulence factors and immune evasion mechanisms used by this parasite.

In spite of the non-invasive nature and controvert pathogenicity of *Blastocystis* spp., local-intestinal and systemic immune responses have been observed, but are somewhat conflicting. In symptomatic humans, higher levels of serum IgG have been found than in asymptomatic individuals, with variable levels of IgA in serum (Mahmoud and Saleh, 2003; Zierdt et al., 1995). On the other hand, mucosal antibody response in the intestine, mediated by secretory IgA (Fig. 4C), seems to be associated with latent infection, because this isotype is more abundant both in symptomatic patients and in immunized BALB/c mice, acting as a first-line defense against attachment and invasiveness by *Blastocystis* (Mahmoud and Saleh, 2003; Santos and Rivera, 2009). Further, in pigs, where ST1, ST3 and mainly ST5 predominate, a study testing IgA by immunoblot in 233 fecal samples from asymptomatic, PCR-positive pigs revealed 81% reactivity against different protein bands of a *Blastocystis* extract from isolate WR-1 (ST4), particularly against a 250 kDa component (Wang et al., 2014). In this context, recent experiments have identified an important role for secreted proteases as major candidate for virulence factors based on their ability to degrade secreted antibodies, disrupt epithelial barrier function and promote the production of pro-inflammatory cytokines (Ajjampur and Tan, 2016; Nourrisson et al., 2016). Particularly cysteine proteases of *Blastocystis* from symptomatic human cases displayed a higher enzyme activity than those from asymptomatic carriers (Mirza and Tan, 2009). Indeed, secretory dimeric IgA was degraded by cellular and secretory *Blastocystis* proteases of the cysteine (isolate B, ST7) and a aspartic protease (isolate WR-1, ST4) (Puthia et al., 2005). Interestingly, a variant repertoire and activity of cysteine proteases within and among STs have been reported (Gentekaki et al., 2017; Mirza and Tan, 2009), supporting the notion of variability in pathogenicity and in immune evasion ability among STs.

NO is an important component of the innate immune system, which is produced in large quantities from L-arginine through the activation of NOSII, and is a free radical causing nitrosative stress-mediated death in microbial pathogens. In *Blastocystis*, necrosis as well as apoptosis-like processes might be induced by NO (Eida et al., 2008; Mirza et al., 2011b) (Fig. 4D). Interestingly, *Blastocystis* isolate B (ST7) is more prone to apoptosis (i.e., more susceptible to NO) than isolate WR-1 (ST4) (Eida et al., 2008); nevertheless, the ST7 isolate is able to downregulate NOSII mRNA levels in colonic epithelial cell monolayers (CaCo-2) (Mirza et al., 2011b). Although the ST7 isolate contains much higher arginase activity than ST4 isolate, this feature is thought to be secondary to the decrease in NOSII expression in evasion (Mirza et al., 2011a).

Cellular immune response elicited by *Blastocystis* spp. has been studied in vitro and in vivo. The ability of this parasite to disrupt intestinal barrier integrity allows its secreted antigens to cross epithelium and reach the lamina propria, thus reaching effector cells. In this context, cysteine proteases released by *Blastocystis* negatively affect enterocyte junctions through Rho kinase activation, F-actin rearrangement and ZO-1 distribution increasing epithelial permeability (Mirza et al., 2012; Puthia et al., 2006). Experimental infections with cysts in BALB/c mice (human isolate) and rats (isolate RN94-9, ST4) showed, by histological examination, an intense infiltration of pro-inflammatory cells in colonic and caecal mucosa, with a moderate increase in goblet cell numbers (Iguchi et al., 2009; Moe et al., 1997). This recruitment is, in part, mediated by soluble mediators acting on inducing granulocytes/macrophages (GM-CSF) and neutrophil recruitment (IL-8), both released by colonic epithelial cell lines (HT-29 and T84) in response to infection by *Blastocystis* (Long et al., 2001). Regarding mucus production by goblet cells that alleviate colitis-induced symptoms, this production is triggered via IL-22 from CD4⁺ cells (Leung et al., 2014). In addition, macrophages initially resident in the lamina propria or recruited to the inflamed bowel may be induced by serine proteases from *Blastocystis*, which may activate protease-activated receptor 2 (PAR2), which, in turn, triggers mitogen-activated protein kinase (MAPK) pathways involving ERK1/2 and JNK, thereby promoting the expression of pro-inflammatory cytokines as IL-1 β , IL-6 and TNF α (Lim et al., 2014) (Fig. 4E). Interestingly, this response was found to be more intense when macrophages and even mice with colitis or mouse colon explants were exposed to lysates from isolate B (ST7) as compared with isolate WR-1 (ST4), indicating a differential pro-inflammatory potential among STs (Lim et al., 2014). Further, some IBS cases with concomitant *Blastocystis* infection are refractory to metronidazole treatment, as parasite isolates (e.g., isolate B) display resistance to this drug (Mirza et al., 2011a). Moreover, isolate B has a higher virulence-arsenal than isolate WR-1, as it contains more cysteine and serine proteases, and arginase activities that appear to explain isolate B's higher IgA degradation capacity, higher phosphorylation of MAPKs leading to higher pro-inflammatory responses and lower NO production in host cells to allow parasite survival.

The relationship between cellular immune responses to *Blastocystis* and development of intestinal inflammation, i.e., IBS/IBD, is unclear, but there are significant insights into the activation of the immune response, loss of tolerance to the parasite and immunosuppression (Kaser et al., 2010; Strober et al., 2002). In IBS patients with concomitant *Blastocystis* infection, lower levels of CD3⁺ and CD4⁺ cells and CD4⁺/CD8⁺ ratios were observed (Wang et al., 2002) (Fig. 4F). In the same context, IBS patients infected with subtypes ST1 or ST3 produced higher levels of pro-inflammatory cytokines as IL-8, IL-12 and TNF α compared to patients with only IBS (Yakoob et al., 2014) (Fig. 4G). In addition, *Blastocystis* carriers harbouring polymorphisms in the alleles of pro-inflammatory IL-8 + 396 (GG) and anti-inflammatory IL-10-592 (C) cytokines were at significant risk of developing IBS (Olivo-Diaz et al., 2012) (Fig. 4H).

Besides pro-inflammatory cytokines, there is limited information regarding other soluble parasite mediators. Interestingly, colorectal cancer cell line HCT116 exposed to antigen extracts of *Blastocystis* from symptomatic patients significantly up-regulated transcription factor NF- κ B, Th-1 (IFN- γ and TNF α) and Th-2 (IL-6, IL-8 and TGF β) mRNA responses with dominance of Th-2 pattern in comparison with the same cells exposed to extracts from asymptomatic patients (Chan et al., 2012). Considering this aspect, a

comparison among subtypes ST1 to ST5 showed that ST3 evoked a higher up-regulation of Th-2 cytokines, particularly TGF β (Kumarasamy et al., 2013). Altogether, these observations provide evidence of host immunomodulation induced by this parasite.

Immune responses in immunocompromised hosts

It is recognised that infection by *Blastocystis* spp. is more effectively counteracted by mixed Th-1/Th-2 cytokine responses, since this parasite is classically extracellular (Daugelat and Kaufmann, 1996). Nevertheless immunomodulation may occur at multiple levels in immunocompetent (IC) hosts (i.e., sIgA destruction, proinflammatory cytokine production, NOSII down-regulation, Th-2 dominance), raising questions about the outcome of immune response in infected immunocompromised hosts. In this context, experiments in BALB/c mice treated with dexamethasone-induced immunosuppression (IS) have provided interesting evidence. Here, the survival rate of IS mice infected with cysts from human carriers (presumably ST3) decreased by 50% from 5 days post-infection and, remarkably, parasite vacuolar forms infiltrated more severely the epithelial, lamina propria, submucosa and mucosa layers of IS-mice, possibly by an invasive mechanism (Abdel-Hafeez et al., 2016). These mice also showed an up-regulation of pro-inflammatory cytokines (IL-12 and TNF α) and downregulation of anti-inflammatory cytokines (IL4 and IL-10) as compared with IC-mice, suggesting a likely influx of macrophages, T cells and/or NK cells and an exacerbated inflammatory response (Abdel-Hafeez et al., 2016; Iguchi et al., 2009). On the contrary, sIgA levels in the gut were downregulated in IS mice as compared to IC-mice, allowing the permanence of parasites at intestinal tract (Abdel-Hafeez et al., 2016). In other studies, the expression of regulatory cytokines, such as IL-17 and IL-23, was higher in the small and large intestines of *Blastocystis*-infected IS-mice than in non-infected IS- and IC-mice (Wu et al., 2012). These studies indicate a more severe pathology and inflammatory responses in immunocompromised mice, but it remains to be established whether this is the case in humans. An integrative scheme summarising current knowledge of immune response mechanisms in immune and immunopathological responses to *Blastocystis* infection is shown in Fig. 4.

Microbiota changes and *Blastocystis* infection, a role for host immunity?

The inventory and diversity of prokaryotic gut microbiota in humans infected by *Blastocystis* spp. vary depending on the outcome of infection. In infected carriers, when compared to non-infected ones, a more diverse microbiota with higher abundance of *Clostridia* and lower abundance of *Enterobacteriaceae* was observed (Audebert et al., 2016) as well as a reduced frequency of *Blastocystis* in stools from patients with *Bacteroides*-rich microbiota (Andersen et al., 2015). In infected patients with IBS and constipation a decrease in protective and anti-inflammatory flora, i.e., *Bifidobacterium* spp. and *Faecalibacterium prausnitzii*, was observed (Nourrisson et al., 2014). Interestingly, the carriage of *Blastocystis* in patients with IBS and diarrhoea was not associated to altered fecal microbiota (Nagel et al., 2016).

From these observations, there is likely a complex interplay of immunomodulatory processes as a consequence of the coexistence of *Blastocystis* and bacterial communities in the gut. On one side, a Th-2-dominant response in asymptomatic carriers decreases cellular responses, such that more bacterial species remain in the host gut. On the other, infected individuals with concomitant IBS-constipation might display a dominant pro-inflammatory response and an inhibition of NO production that affect intestinal peristalsis and ultimately hinder the survival of anti-inflammatory flora. Nevertheless, unaltered microbiota in IBS-diarrhoea spectrum is a challenging issue that deserves serious attention. Further, effects of resident microbiota on the expression of possible virulence factors of *Blastocystis*, e.g., protease secretion, warrant future studies.

Concluding remarks

In this century, efforts to improve the control for neglected tropical diseases, such as soil-transmitted helminths and gastrointestinal protozoa inhabiting the intestinal tracts of humans and other animals (i.e., IUP), have been enabled through the use of “next-generation” tools, including sophisticated immunological methods, genome sequencing and molecular engineering strategies, applied at the in vitro- and in vivo-levels and employing valuable experimental models to assess host-pathogen interactions, immunity and the pathogenesis of disease. Importantly, these tools have been used to gain basic knowledge and understanding of mechanisms involved in host innate and adaptive immune responses, immunopathological outcomes and intricate interactions between pathogens and bacterial communities in the host gut. This framework has offered a solid foundation for gaining deep insights into fundamental aspects of the immunobiology of protistan pathogens and for applied aspects, such as the design of new strategies aimed at prevention or protection against related diseases.

In spite of the current absence of prophylactic biologicals against human giardiasis, amebiasis, cryptosporidiosis and blastocystosis, immunological investigations are providing new insights into immunoprotective responses. Thus, a paradigm regarding “predominant Th-1 responses supported by Th-2-dependent processes” to eliminate unicellular intestinal pathogens is now a consensus. Novel candidate molecules are emerging for the development as vaccines against selected unicellular intestinal parasites; these include the secreted proteins of *G. duodenalis* (e.g., giardins, VSPs, giardipain-1), secreted proteases from *Blastocystis* spp., sporozoite surface proteins of *Cryptosporidium* and surface lectins (galectins) of *E. histolytica*, although progress differs depending on parasite. However, an ample repertoire of strategies for vaccine design and delivery, from DNA-based vaccines to live-attenuated

bacterial vectors, is now available to make significant progress. These promising elements point towards an acceleration of progress to develop effective methods and reagents for the prevention, treatment and/or control of some of these insidious protistan diseases.

Acknowledgments

We are immensely grateful to Robin B Gasser for his comments, technical and language editing of the manuscript. We are grateful to Arturo Pérez-Taylor for his help in the art work and informatics support. We would like to acknowledge support from Fondo SEP-Cinvestav Mexico and from Consejo Nacional de Ciencia y Tecnología (SEP-CONACYT) Mexico, Grant number A1-S-39422 (to GOP) and Grant number 284830 (to JCC). JCC also thank Programa de Apoyo a Proyectos de Investigación e Innovación Tecnológica-Universidad Nacional Autónoma de México (PAPIIT-UNAM) for grant No. IN206316.

Glossary

Calabar swelling A transient subcutaneous swelling marking the migratory course through the tissues of *Loa loa* adult worms.

Hydrocele Accumulation of lymph fluid in the scrotum of men during lymphatic filariasis.

Macrofilaricide A drug that kills adult filariae.

Microfilariae Progeny of the filarial nematodes.

Microfilaricide A drug that kills microfilariae.

Onchocercoma Subcutaneous nodule that contains the adult *Onchocerca volvulus* worms.

Sheath Microfilariae cover of some filarial species.

Sowda Severe, unilateral form of dermatitis in onchocerciasis patients.

Wolbachia Endosymbiotic bacteria of some filarial species.

Onchocerciasis

Short overview

Onchocerciasis is listed by the WHO as a neglected tropical disease (NTD) and is caused through infection with the filarial nematode *Onchocerca volvulus* which is transmitted by bites of *Simulium* blackflies. Although the majority of infections show few or light symptoms, the disease can lead to severe clinical symptoms like vision loss, blindness and dermatitis including the unilateral, severe form sowda. Since breeding sites of the black flies are usually found in fast-flowing oxygen-rich rivers and creeks, transmission and disease prevalence stretch along these rivers and thus onchocerciasis is often referred to as river blindness.

Biology/Etiology

The life cycle of *O. volvulus* consists of two hosts, the human as definite host and *Simulium* black flies as intermediate host. Thus, the life cycle of *O. volvulus* is comparable to other human-pathogenic filariae, with humans that harbor the adult worms and transmitting blood-feeding insect vectors (Fig. 1). Female *Simulium* blackflies can transmit infective larvae (L3 stage) during the blood meal into the human body. Until now little is known about the fate of L3 in the human skin but L3 molt once to become L4 within 10 days. The L4 persist in the host and develop into adult worms within 6–12 months. Female (33–50 cm long and 270–400 µm wide) and male adult worms (19–42 mm length and 130–210 µm wide) reside in subcutaneous nodules, also called onchocercomata, that are commonly located around the iliac crest, but also the head and torso (Brattig et al., 2020; Murdoch, 2021). Adult worms are also able to migrate freely in the subcutaneous tissue. Females and males reside in a ratio of approximately 3:1 in the onchocercoma and mate. Consequently, gravid female worms produce thousands of first stage unsheathed larvae (L1), the so-called microfilariae (MF; “offspring”; 220–360 µm long and 5–9 µm wide) that are released into the subcutaneous tissue (Schulz-Key, 1990). They can sometimes be found in blood, urine or other fluids such as lymphatics (Mackenzie et al., 2010), especially in individuals with high worm burdens. It is estimated that the reproductive life span of female worms can achieve 9–11, sometimes 15 years, and even MF may live for several years in dermal tissue (Specht et al., 2009; Udall, 2007) i.e., the dermal papillae just below the epidermis. The migrating MF can be taken up and ingested by black flies during a subsequent blood meal. In the black fly the MF penetrate the peritrophic membrane of the midgut and migrate through the haemolymph where they settle in the syncytial cells of the thoracic longitudinal flight muscles. Within 1–2 weeks, the MF molt twice to become infective L3, which can be transmitted via another blood meal by the blackfly into the human body (Brattig et al., 2020; Murdoch, 2021). As most human pathogenic filariae, *O. volvulus* contain endosymbiotic *Wolbachia* bacteria that are found in the hypodermis and embryonal stages of the filariae. *Wolbachia* are essential for filarial development, embryogenesis and survival (Taylor et al., 2005).

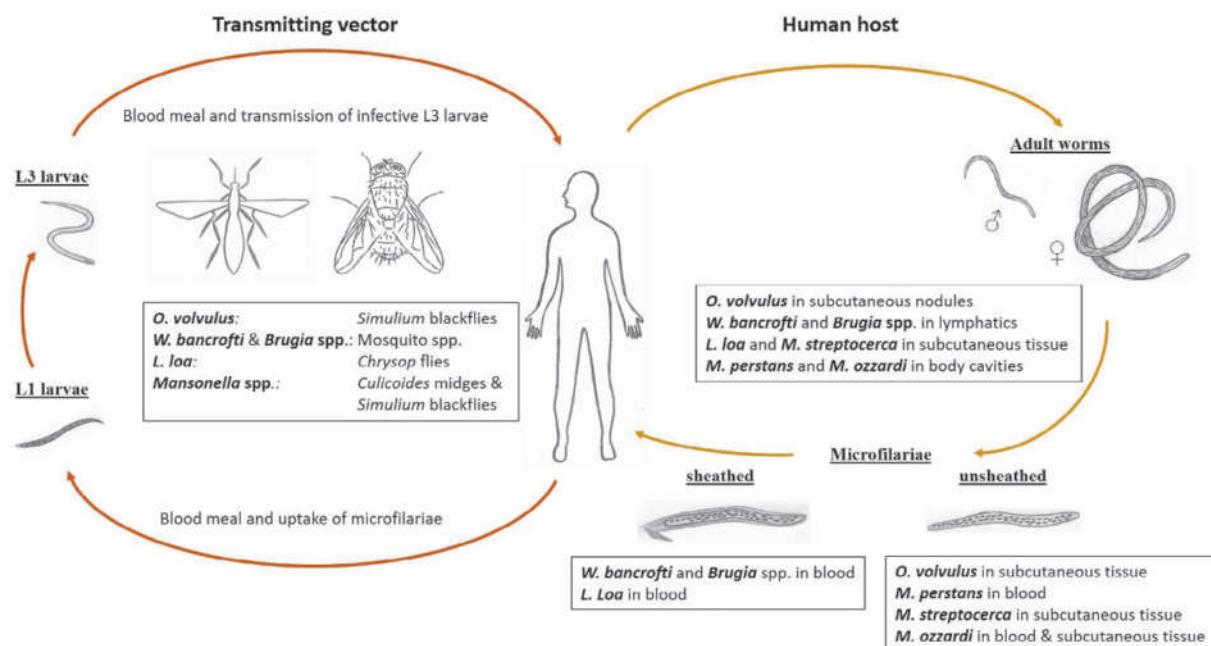

Fig. 1 Generalized life cycle of human pathogenic filariae.

Epidemiology

As mentioned above, onchocerciasis predominantly affects people living close (12 km) to rivers that serve as breeding grounds for the *Simulium* blackflies. Several subspecies serve as vector but *S. damnosum* is the predominant vector in Africa and *S. neavei* blackflies also drive transmission in East and Central Africa (Fischer et al., 1993, 1997b; Makunde et al., 2000). According to the Global Burden of Disease study 2017, approximately 21 million people are infected worldwide (Global Burden of Disease Study 2017, 2018) and more than 218 million individuals live in endemic areas and are at risk of infection. Moreover, approximately 15 million of the infected people suffer from skin disease and more than 1.2 million from vision loss leading to approximately 205 million disability-adjusted life years (DALY's) (Global Burden of Disease Study 2017, 2018). Onchocerciasis is prevalent in tropical areas but 99% of infected people live in 31 Sub-Saharan African countries named Angola, Benin, Burkina Faso, Burundi, Cameroon, Central African Republic, Chad, Republic of Congo, Côte d'Ivoire, Democratic Republic of the Congo, Equatorial Guinea, Ethiopia, Gabon, Ghana, Guinea, Guinea-Bissau, Kenya, Liberia, Malawi, Mali, Mozambique, Niger, Nigeria, Rwanda, Senegal, Sierra Leone, South Sudan, Sudan, Togo, Uganda, United Republic of Tanzania. Detailed data and maps about the prevalence of onchocerciasis and elimination programmes can be obtained from the Expanded Special Project for Elimination of Neglected Tropical Diseases (ESPEN; <https://espen.afro.who.int/>; Rebollo et al., 2021). Due to mass drug administration (MDA) programmes, onchocerciasis transmission could be interrupted in Ecuador, Colombia, Mexico and Guatemala. Onchocerciasis transmission areas in America only remain in a remote cross-border region between Venezuela and northern Brazil including approximately 34,000 people (WHO, 2020c).

Epidemiology of onchocerciasis depends on vector abundance, competence and feeding characteristics, parasite strains as well as host ethnicity, heritability and immune responses as well as socio-economic factors like occupation, seasonal migration, income and social standing. Although susceptibility of men and women is comparable, there is evidence that children from *O. volvulus*-infected mothers are more susceptible to infection since they get infected in earlier life and have higher MF in the skin compared to children from non-infected mothers (Kirch et al., 2003). It is suggested that during pregnancy of infected women the filariae-induced immunosuppression towards *O. volvulus* is passed to the fetus and shapes its susceptibility to *O. volvulus* infection.

Onchocerciasis endemicity is classified in hypoendemic, mesoendemic or hyperendemic areas according to the MF prevalence rates of <40%, 40–59% and >60%, respectively. Based on transmission infection and disease data sets, mathematical models can characterize transmission dynamics (Basanez et al., 2016; NTD Modeling Consortium Onchocerciasis Group, 2019) and are a useful tool to predict the effects of treatment and vector control programmes.

Pathology

The majority of *O. volvulus*-infected individuals remain with few symptoms such as mild dermatitis and are referred to as generalized onchocerciasis (GEO); this status includes onchocercomata formation under the skin (Fig. 2A and B), high parasite burden and weak skin inflammation. Onchocercal nodules are normally 0.5–3 cm in diameter (Fig. 2C) and constitute granulomatous reactions that can be separated in chambers with thick fibrous walls and a variable degree of cellular infiltration around the adult worms (Fig. 2D), consisting of macrophages, neutrophils and eosinophils (Brattig et al., 2001; Korten et al., 1998). These nodules can degenerate, calcify and cause scarring and atrophy (Albiez et al., 1988; Burchard et al., 1979; Büttner et al., 1988; Lupi et al., 2015) (Fig. 2E). Cutaneous onchocerciasis can induce various skin pathology manifestations like acute and chronic papular dermatitis that can lead to skin hyperpigmentation (Fig. 3A) or depigmentation (leopard skin) (Fig. 3B) and atrophy with loss of elasticity (hanging groin) (Murdoch et al., 1993). Early symptoms of onchocercal dermatitis are itching and rash due to dying or dead MF that can disappear within a couple of days. However, the rash can persist and result in intense pruritus accompanied with secondary bacterial or fungal infections due to scratching. Consequently, repeated acute inflammation due to dying MF can lead to chronic onchodermatitis including large papules. In severe cases this leads to lichenification and thickening of skin, so called lizard skin, and depigmentation and hyperpigmentation, so called leopard skin (Fig. 3A and B), that can be used as epidemiological marker for onchocerciasis-endemic areas. However, the severest form of symptoms and skin diseases including dermatitis is sowda (Fig. 3C), which is characterized by pruritic hyperpigmented hyperkeratotic plaques, often asymmetrical and localized, associated with local lymphadenopathy (Edungbola et al., 1987; Katawa et al., 2015; Murdoch et al., 1993; Njim et al., 2015). This disease manifestation is called hyperreactive onchocerciasis (HO) and individuals suffering from HO normally present low parasite burden.

In addition, *O. volvulus* infection can cause vision loss due to immune responses against MF in the anterior and posterior segments of the eye (Abiose, 1998; Tamarozzi et al., 2011) (Fig. 4). Until now, the entry route of the MF into the eye is not clear, but it is suggested that blood sheaths of the posterior ciliary arteries and nerves, cerebrospinal fluid, as well as the sheath of the optic nerve serve as entry point (Basak et al., 2007; Budden, 1976). Dying MF release *Wolbachia* endosymbionts causing the infiltration and activation of fibroblasts, dendritic cells and macrophages that induce chemokine-based recruitment of neutrophils. Neutrophil-driven immune responses degrade the corneal matrix, causing corneal haze and visual impairment, edema and opacity (Tamarozzi et al., 2011). With regards to the posterior segment, the mechanisms leading to optic nerve atrophy and chorioretinitis are not fully understood. Interestingly, persistent deterioration in the posterior segment was also shown in individuals despite repeated ivermectin treatment and clearance of MF (Banla et al., 2014; Semba et al., 1990). It is suggested that autoimmune responses, i.e., cross-reactive antibodies to retinal pigment epithelial antigen, or persistence of MF or their products may play a role for posterior segment diseases (Braun et al., 1991; Chandrashekar et al., 1990).

Fig. 2 Onchocercomata. (A and B) Arrows mark onchocercomata under the skin including pustular dermatitis in (B). (C) Isolated intact onchocercoma and (D) cut open onchocercoma showing adult *O. volvulus* filariae and (E) calcified adult worms. The scale bar shows cm. (C–E) Nodules were obtained during the MoRiOn study (ISRCTN43697583).

Fig. 3 Papular dermatitis during onchocerciasis. (A) Hyperpigmentation and lichenification, (B) leopard skin and (C) unilateral hyperreactive onchodermatitis (left leg), termed sowda.

Finally, onchocerciasis is associated with two forms of epilepsy, called onchocerciasis-associated epilepsy and nodding syndrome characterized by paroxysmal head nodding (Colebunders et al., 2019; Vieri et al., 2021), as well as with Nakalanga syndrome that is characterized by growth arrest and delayed sexual development (Kipp et al., 1996; Newell et al., 1997); the mechanisms how *O. volvulus* infection induces these diseases remains unclear.

Fig. 4 Onchocerciasis-driven sclerosis of the cornea. (A) Onset of cornea sclerosis and (B) advanced sclerosing keratitis leading to vision loss.

Immunology and immunomodulation

As mentioned above, the majority of *O. volvulus*-infected individuals, i.e., those with generalized onchocerciasis (GEO), have few and mild symptoms; they tend to have high skin MF with low tissue reaction accompanied with the absence of clinical symptoms. Host immune responses of GEO individuals are regulated through the induction of regulatory T cell subsets, immunomodulatory IgG4 as well as IL-10 and TGF- β leading to suppression of effector mechanisms associated with parasite survival and MF release (Arndts et al., 2014; Doetze et al., 2000; Hoerauf and Brattig, 2002; Satoguina et al., 2002). It has been shown that the down-regulation of host immune responses impairs *Mycobacterium tuberculosis* (BCG) and tetanus vaccination efficacy and reduces immune response to allergens (Cooper et al., 1999; Kilian and Nielsen, 1989a,b). However, as mentioned above *O. volvulus*-infected individuals can suffer from severe disease; especially hyperreactive onchocerciasis (HO) individuals are characterized by increased effector mechanisms such as induction of IgE and Th1, Th2 and Th17 immune responses and suppression of regulatory cell subsets and immune responses (Hoerauf and Brattig, 2002; Katawa et al., 2015). The effector immune responses successfully eliminate MF from the skin but simultaneously elicit severe dermatitis and sowda, which is suggested to depend on genetic predisposition and the IL-13 gene (Hoerauf et al., 2002).

Diagnosis

Clinical manifestations of onchocerciasis are subcutaneous nodules, dermatitis, skin and eye lesions. The adult-worm containing nodules are usually mobile and painless. In sub-Saharan Africa their location is mainly around the hip region, calves and thorax (Hoerauf, 2011). For parasitological diagnosis MF can be detected from skin snips and adult worms from nodules. Diagnosis of *O. volvulus* adult worms via ultrasound (Mand et al., 2005) or histology from extracted nodules (Hoerauf et al., 2008) requires expertise and therefore MF diagnosis is the gold standard. In general, the iliac crest is the preferred site to diagnose MF. For MF diagnosis, 2–4 skin snips are taken with a 2 mm Holth corneoscleral punch or razor and transferred to phosphate buffered saline containing wells of a 96-well plate, where MF migrate out of the tissue within 24 h and can be microscopically quantified (Nutman et al., 1996). The unsheathed *O. volvulus* MF have to be distinguished from *M. streptocerca* in co-endemic areas in Sub-Saharan Africa and *M. ozzardi* in co-endemic areas in South-America. Contamination of skin snips with blood has to be avoided to exclude filarial species with blood-dwelling MF (e.g., *W. bancrofti*, *Brugia* species, *L. loa*). *O. volvulus* MF can also be detected inside the eye using a split lamp. Bending the head forward for 10 min increases the chances to locate the MF in the eye (Hoerauf, 2011). In general, *O. volvulus* MF are most often found in residents from endemic areas that are not under MDA, while non-resident travelers often develop amicrofilaridemic infections. For serological analysis a commercially available rapid-format antibody card test is available that detects IgG4 antibodies against the *O. volvulus* Ov-16 recombinant antigen (Lipner et al., 2006). Furthermore, several molecular tests are available to detect DNA from *O. volvulus* in skin snips and *Simulium* blackflies via either PCR-based methods (Lloyd et al., 2015; Prince-Guerra et al., 2018) or field-applicable Loop-mediated isothermal amplification (LAMP) (Abong et al., 2020, 2021; Poole et al., 2017).

Intervention/Therapy

In accordance with the United Nations Sustainable Development Goals on health, the WHO Neglected Tropical Disease roadmap 2021–30 stated as target for onchocerciasis the confirmed elimination of transmission by 2030 (WHO, 2020a, c). The current intervention relies on the distribution of MDA with ivermectin in endemic areas (WHO, 2020c).

Ivermectin is a macrocyclic lactone that is given as a single oral dose of 150 µg/kg. Ivermectin clears the majority of MF within a few days after treatment and temporarily inhibits the embryogenesis of the adult *O. volvulus* female worms (Awadzi et al., 1989; Gardon et al., 2002). Thus, the release of MF and the transmission of onchocerciasis is interrupted for several months (Duke et al., 1991). However, since ivermectin is not macrofilaricidal—does not kill the adult worms—MDA has to be repeated every 6–12 months for the reproductive life-span of *O. volvulus*, i.e., 10 years and more, to eliminate the transmission of the disease. Contraindications of ivermectin treatment in pregnant or breast-feeding women with children less than 1 week of age as well as children below 90 cm of height, migrating populations, discontinuous or sub-coverage MDA and areas that showed suboptimal ivermectin efficacy further hamper the efforts to eliminate onchocerciasis by ivermectin MDA. Most common adverse events following ivermectin treatment are caused by the dying MF and consist of inflammatory immune responses leading to itching skin, rash, fever, and/or headache (Whitworth et al., 1988). Importantly, in comparison to diethylcarbamazine (DEC), adverse events caused by ivermectin treatment are less severe, and while permanent vision impairment can occur following DEC treatment in onchocerciasis patients, this is not the case with ivermectin (Greene et al., 1985). Thus, DEC is contraindicated for treatment of onchocerciasis patients. More recently, moxidectin, another macrocyclic lactone, was introduced for onchocerciasis treatment. Similar to ivermectin, moxidectin clears MF, temporarily inhibits filarial embryogenesis and has no macrofilaricidal efficacy (Awadzi et al., 2014; Opoku et al., 2018). However, in comparison to ivermectin, moxidectin leads to an extended absence of microfilaridermia, which lasts for up to 1 year (Opoku et al., 2018).

The only well-tolerated macrofilaricidal drug for onchocerciasis so far is doxycycline (Hoerauf et al., 2000, 2001; Walker et al., 2015). Doxycycline targets the *Wolbachia* endosymbionts of *O. volvulus* and by depleting these endosymbionts doxycycline therapy leads to a permanent inhibition of filarial embryogenesis and death of the adult worms after 1.5–2 years (Hoerauf et al., 2003, 2008, 2009). Doxycycline treatment does not cause MF-induced adverse events, as it has no or only little effect on the MF itself, and MF clearance over time is only due to the natural removal of MF and the inhibition of filarial embryogenesis. To achieve the macrofilaricidal efficacy, doxycycline has to be given for 6 weeks with 200 mg/day (Hoerauf et al., 2008; Turner et al., 2010; Walker et al., 2015). To achieve permanent sterility and permanent amicrofilaridermia, doxycycline treatment with 200 mg/day for 4 weeks or 100 mg/day for 5 weeks are sufficient (Hoerauf et al., 2008, 2009; Walker et al., 2015). In order to accelerate the clearance of MF, doxycycline treatment can be combined with a single dose of ivermectin (Hoerauf et al., 2001; Turner et al., 2010). Doxycycline is now recommended by the WHO as individual therapy and in mopping up remaining foci in the Americas (WHO, 2019). Although the extended treatment with doxycycline over several weeks prevents its broader use for MDA and its use is contraindicated in pregnant, breast-feeding women and children below the age of 8, doxycycline treatment confirmed the efficacy of anti-wolbachial drugs.

Currently, research is performed to identify anti-wolbachials that allow shorter treatment regimens. The Tylosin analog ABBV-4083 is such an anti-wolbachial candidate (Taylor et al., 2019) that was recently tested in phase 1 clinical trials, and phase 2 clinical studies in onchocerciasis patients are ongoing. Similarly, high dose rifampicin treatments with 30–35 mg/kg/day are predicted to be superior to doxycycline treatment (Aljayyousi et al., 2017; Specht et al., 2008) and are currently tested in phase 2 clinical studies. Two additional macrofilaricidal candidates are the direct-acting cyclooctadepsipeptide emodepside (Krücken et al., 2021) and the benzimidazole oxfendazole (Hübner et al., 2020), which both passed phase 1 clinical studies. Emodepside is currently evaluated in phase 2 clinical studies in onchocerciasis patients.

A summary of the key facts for onchocerciasis covered in this chapter is presented in Table 1.

Lymphatic filariasis

Short overview

Lymphatic filariasis (LF) is listed by the WHO as neglected tropical disease (NTD) and is caused by infection with the filarial nematodes *Wuchereria bancrofti*, *Brugia malayi* and *B. timori*. LF is the second leading infectious cause of disability worldwide after leprosy. The disease impairs the lymphatic system and can lead to severe clinical manifestations such as hydrocele, lymphedema and elephantiasis, causing a major public health problem and an overall increase in disability-adjusted life years (DALYs) in endemic countries.

Biology/Etiology

Three species of the lymph-dwelling filarial nematodes, named *W. bancrofti*, *B. malayi* and *B. timori* cause LF in humans and so far, no major reservoir host is known, except for a zoonotic habitat in South Thailand. The disease is transmitted by mosquito species including the genera *Aedes*, *Anopheles*, *Culex* and *Mansonia* (Manguin et al., 2010). *B. timori* is transmitted by *Anopheles barbirostris* (Atmosoedjono et al., 1977), *B. malayi* by *Mansonia* and *Anopheles* spp. (Bizhani et al., 2021). 90% of LF infections are caused by *W. bancrofti* during a bite of all mentioned mosquito spp. (Fig. 1). During the blood meal of the mosquito, infective L3 (1.5 mm in length and 18–23 µm in diameter) are transmitted and migrate to the lymphatics, where they molt and become adult worms within a period of 5–18 months. Female *W. bancrofti* worms are 8–10 cm long and 0.24–0.30 mm in diameter, while males are 4 cm long and 1 mm in diameter. In contrast, *Brugia* adult worms are smaller and female worms measure 4.3–5.5 cm in length and

130–170 μm in diameter, while males are 1.3–2.3 cm long and 70–80 μm width. Gravid female worms release sheathed MF (*W. bancrofti*: 244–296 μm long and 7.5–10 μm wide; *Brugia spp.*: 177–230 μm long and 5–7 μm wide) in the lymphatic vessels that drain into veins entering the blood stream. Interestingly, MF release in the blood stream follows a nocturnal or diurnal periodicity that corresponds to the biting behavior of the vector in the endemic area. In most areas endemic for *W. bancrofti* and *B. malayi* a nocturnal periodicity and peak in MF numbers in the peripheral blood around midnight are prevalent (Simonsen et al., 1997), however, transmission by day biting (diurnal) has been shown in the Pacific region (Moullia-Pelat et al., 1993), with mainly *Aedes* mosquitoes, especially *Ae. polynesiensis*. Female worms live for 5–10 years and produce MF that have a lifespan of 6–24 months (Stolk et al., 2006). These MF are ingested by female mosquitoes during a blood meal. When MF reach the mosquito's stomach, they lose their sheaths and migrate to the midgut to reach the thoracic muscles. Consequently, they molt twice to become infective L3 that migrate through the haemocoel to the mosquito's proboscis where they are transmitted to the human host during a blood meal of female mosquitoes (Bizhani et al., 2021; Edeson, 1972; Nutman and Kazura, 2011; Srividya et al., 2019).

Epidemiology

Since the launch of the Global Programme to Eliminate Lymphatic Filariasis (GPELF) more than 8.2 billion treatments have been distributed between 2000 and 2019. This decreased the population at risk for LF to approximately 858 million people in 49 countries worldwide and led to a reduction of infections and even elimination in Togo, Egypt, Maldives, Sri Lanka, Thailand, Cambodia, Cook Island, Marshall Islands, Niue, Palau, Tonga, Vanuatu, Vietnam, Wallis, Futuna, Japan, Korea and China (Cheun et al., 2009; De-Jian et al., 2013; WHO, 2020b). Currently it is estimated that 65 million individuals are infected with LF and that 19 million hydrocele and 17 million lymphedema cases exist, leading to 1.3 million DALYs (Global Burden of Disease Study 2017, 2018; Ramaiah and Ottesen, 2014; WHO, 2020b). Approximately 90% of LF infections are caused by *W. bancrofti* that occurs in tropical regions of South and Southeast Asia, Africa, the Americas, Middle East and the Pacific, whereas *B. malayi* is found in India, Indonesia, Thailand, Malaysia, and the Philippines. *B. timori* is restricted to islands in Eastern Indonesia (Local Burden of Disease Neglected Tropical Diseases Collaborators, 2020; Michael and Bundy, 1997; Rebollo and Bockarie, 2013). Nevertheless, epidemiology of LF strongly depends on the available habitat, vector capacity and mosquito density, and distribution is often focal so that transmission rates can vary strongly between the communities and even households (Bockarie et al., 2009; Rwegoshora et al., 2007).

Pathology

Although the majority of infected individuals remain asymptomatic and do not develop clinical symptoms, LF can lead to severe clinical symptoms. The most common clinical symptoms of LF are hydrocele (only *W. bancrofti*), lymphedema of the legs, lymphangitis, and elephantiasis (Rebollo and Bockarie, 2017; WHO, 2001). The presence of worms (including *Wolbachia* endosymbiotic bacteria) and their products in the lymphatic system induce endothelial cell proliferation and dilatation of lymphatic vessels (lymphangiectasia) that is mediated by host proteins such as vascular endothelial growth factors, angiopoietin and matrix metalloproteinases. The development of lymphedema is associated with genetic risk factors, and nucleotide polymorphisms for the above genes in the human host have been identified, explaining, at least in part, the clustering in families (Bennuru and Nutman, 2009; Debrah et al., 2006, 2017; Taylor, 2003). Due to the impaired lymphatic function of the dilated lymph vessels, lymph is no longer normally pumped against gravity (similar to venous stasis), resulting in elevated tissue pressure. This can lead to lesions at the skin of the affected leg, which allow secondary bacterial and fungal infections facilitating acute dermatolymphangioadenitis (ADLA) attacks that accelerate the progression of chronic lymphedema development and elephantiasis of the lower extremities (Dreyer et al., 1999a, b, 2006; Olszewski et al., 1999). Progression of lymphedema occurs over periods of years during which leg skin thickens and loses elasticity, develops deep folds accompanied with development of dermatosclerosis and papillomatous “mossy” skin lesions. Lymph fluid may leak from chronic ulcerations in the affected part leading to foul smell of the affected individuals. Moreover, due to rupture of dilated abdominal lymphatic vessels into the upper urinary tract, chyle (and sometimes blood) can be present in the urine (chyluria), leading to weight loss, hypoproteinaemia, lymphopenia and anemia (Gulati et al., 2007). In general, lymphedema is subdivided into seven stages depending on swellings (reversible or non-reversible), leg volume, presence of skin folds, nodules, knobs and lesions (Dreyer et al., 1999b; WHO, 2001) (Fig. 5). Besides lymphedema, hydrocele is a common clinical symptom that affects *W. bancrofti*-infected men due to fluid accumulation inside the tunica vaginalis and swelling of scrotal and groin area (Fig. 6). Acute hydrocele is a result of natural or anti-filarial treatment-induced worm death, leading to acute filarial lymphangitis (AFL) followed by temporally clogging of the lymphatics due to disintegrating worms (Noroes et al., 2003), whereas chronic hydrocele can develop after years of infection due to impaired lymph transport. Migration of adult worms into the scrotal lymphatics and formation of scrotal nodules is regularly observed, with and without hydrocele (Pfarr et al., 2009). Finally, a rare clinical symptom of LF is called tropical pulmonary eosinophilia (TPE). TPE is caused by immunological hyperresponsiveness to MF in the lungs accompanied with paroxysmal coughing and wheezing, extremely high blood eosinophil counts (>3000 cells/ mm^3 of blood) and serum levels of total IgE and antifilarial antibodies that can lead to extrapulmonary manifestations such as splenomegaly, lymphadenopathy and hepatomegaly (Ottesen and Nutman, 1992) or inguinal lymphadenopathy, monoarticular arthritis with pain, warmth and tenderness as well as haematuria and proteinuria (Dreyer et al., 1999a; Sarker et al., 2007).

Fig. 5 Lymphedema stages of lymphatic filariasis. Staging was performed according to Dreyer et al. (2002), based on the presence of swelling, skin folds, knobs and mossy lesions. (A) Stage 2 right leg, (B) stage 3 left leg, (C) stage 4 left leg, (D) stage 5 right leg and (E) stage 6 left leg. Pictures were obtained from the LEDoxy trial (ISRCTN14042737) within the TAKEOFF project (<https://www.gesundheitsforschung-bmbf.de/en/takeoff-filariasis-and-podoconiosis-disease-control-7700.php>).

Fig. 6 Hydrocele from *W. bancrofti*-infected man being prepared for hydrocelectomy.

Immunology and immunomodulation

Despite the fact that individuals in endemic regions are constantly exposed and live with a high risk of infection, a wide range of clinical manifestations and infections status, such as infected MF-positive and infected but MF-negative, as well as uninfected individuals, can be observed. For example, individuals with asymptomatic infections are relatively tolerant to filarial worms and are characterized by strongly regulated and dampened immune responses via the induction of regulatory B and T cell subsets, alternatively activated macrophages and increased secretion of regulatory molecules IL-10, TGF- β and IgG4 that are essential for the long-term survival of filariae and prevent the onset of severe pathology (Adjomey and Hoerauf, 2010; Arndts et al., 2012; Babu et al., 2006; Hoerauf et al., 2005; Metenou et al., 2010; Pfarr et al., 2009; Ritter et al., 2019). Host immune regulation also leads to decreased immune responses to other pathogens and impaired vaccination efficacy (Kroidl et al., 2016; Metenou et al., 2011; Michael et al., 1994; Nookala et al., 2004; Simonsen et al., 2002), but was also suggested to protect against diabetes and controlling autoimmunity and inflammation (Aravindhana et al., 2010a,b; Babu et al., 2006). Indeed, loss of regulation and immune tolerance to filarial worms and activation of host immune responses such as increased Th17 responses and proinflammatory immune responses leads to death of the parasites and collateral damage to lymphatic vessels, showing that the host immune status strongly influences the infection status (Arndts et al., 2012; Babu and Nutman, 2014; Freedman, 1998; Jaoko et al., 2006; Maizels et al., 2009; Ritter et al., 2019). Indeed, most chronic lymphedema patients are no longer infected and accelerated immune responses like increased IgE levels and eosinophils are associated with TPE (Chitkara and Krishna, 2006; Hussain et al., 1981).

Diagnosis

Acute filarial lymphangitis (AFL; reversible after death of adult worms), lymphedema, hydrocele, and the other abnormalities mentioned above are the most prominent pathologies occurring during LF. In order to differentiate them from non-filariae-caused pathologies, parasitological, serological and molecular tests are available.

Classical parasitological diagnosis relies on the detection of MF in peripheral blood. However, detection of MF alone is not a reliable test for the diagnosis of LF, as especially patients with clinical filariasis, i.e., lymphedema or hydrocele, are often amicrofilaremic, whereas MF positive patients are often asymptomatic. Furthermore, the predominant nocturnal periodicity of the MF requires that MF diagnosis is performed from blood collected during the peak of microfilaremia between 21:00–3:00 at night (Simonsen et al., 1997). Microscopic evaluation further requires the differentiation of the sheathed MF of LF from other filariae with blood-dwelling MF such as *M. perstans*, *M. ozzardi* and *L. loa*; this can be achieved via the filarial-species specific arrangement of the nuclei. Besides the routine thick blood smear, concentration methods such as Knott's and membrane filtration are used to increase the sensitivity for MF detection. For example, if MF density is <100 MF/mL blood, a smear using only 10 µL of blood may turn out false negative.

Adult *W. bancrofti* infections can be also detected in the male scrotum via ultrasonography (Mand et al., 2003). The specific movement pattern of the adult filariae is referred to as filarial dance sign within the dilated lymphatic vessels. Ultrasonography further allows the assessment of hydroceles. Detection of adult worms in other locations such as the female breast or inguinal regions as well as *B. malayi* adult worms is not regularly achieved by ultrasonography (Mand et al., 2006).

A big step forward in LF diagnosis has been the introduction of card tests that detect Circulating Filarial Antigen (CFA) released by adult *W. bancrofti* (but not *Brugia*) antigens. Results appear to correlate with adult worm burden (Weil et al., 2013). Importantly, the CFA test is field-applicable, has a hand-on time of approx. 15 min. and does not require blood that is taken at night. Recent data suggest that the CFA test can cause false-positive results in heavily infected *L. loa* patients (Pion et al., 2016). This presents a problem for MDAs, as the CFA test is most commonly used for the mapping of LF endemic areas (WHO, 2011); however, more recent research has found that endemic areas for LF and loiasis do not grossly overlap, due to different habitats of the transmitting vectors. Similar to onchocerciasis, IgG4-detecting antibody tests are also available for LF and they have an increased specificity in comparison to IgG based antibody tests. Recombinant antigens used in those assays are e.g., Bm14 and Wb123 (Steel et al., 2013; Weil et al., 2011). However, while those antibody tests are valid for the diagnosis of expatriates, they are not recommended for people from LF endemic regions, as these individuals have been multiply infected and often possess specific antibodies in the absence of active infection or clinical filariasis.

Several PCR and LAMP assays are also established to diagnose MF DNA from peripheral blood (Poole et al., 2017; Rao et al., 2006). Similar to the microscopic detection of MF, the molecular techniques detecting MF DNA require blood samples that were taken during night. The sensitivity of those molecular tests is comparable to the microscopic techniques.

Intervention/Therapy

The WHO NTD roadmap 2021–30 stated the goal to achieve for LF in 80% of endemic countries the elimination as public health problem by 2030.

Already in the 1990s, annual MDA with ivermectin plus albendazole or DEC plus albendazole were used in combination with mosquito control programs. In 2000, the WHO launched the GPELF with the goal to eliminate LF by 2020. Within GPELF a total of over 8 billion doses were distributed to more than 923 million people by annual MDA treatments with ivermectin plus albendazole or DEC plus albendazole and 17 countries are currently under surveillance for verifying the elimination the LF transmission. While GPELF did not reach the goal of global LF elimination by 2020, it provides a platform that countries can use to sustain their efforts to eliminate LF as public health problem by 2030 (Hooper et al., 2014; Ichimori et al., 2014; Ottesen and Horton, 2020; Ramaiah and Ottesen, 2014; Turner et al., 2016).

Thus, in endemic areas, the main intervention for LF consists of annual, single-dose mass administration of drugs (DEC, ivermectin and albendazole) that are primarily targeting the MF stage. Single-dose oral DEC or ivermectin treatment removes MF from the peripheral blood and inhibits MF release by the adult worms for a few months, but does not efficiently kill the adult worms (Cao et al., 1997; Eberhard et al., 1997). Similarly, a single oral dose of albendazole reduces *W. bancrofti* microfilaremia for several months (Ismail et al., 1998). Over the past decades, combination therapies with DEC plus albendazole (in areas non-endemic for onchocerciasis) or ivermectin plus albendazole (in areas co-endemic for onchocerciasis) were performed as annual MDA. Today, for LF in areas that are not co-endemic for onchocerciasis and loiasis, WHO recommends MDA using “IDA” triple therapy (WHO, 2017) of a single dose of ivermectin (200 µg/kg), DEC (6 mg/kg) and albendazole (400 mg), which reduces microfilaremia for more than 2 years (King et al., 2018; Weil et al., 2019). Furthermore, it is suggested that IDA also has some macrofilaricidal efficacy (Thomsen et al., 2016). The implementation of the triple therapy may be a game changer, as it is expected to reduce MDA rounds. IDA is not recommended in areas that are co-endemic for onchocerciasis or loiasis, since DEC can lead to severe adverse ocular events in onchocerciasis patients and ivermectin caused life-threatening severe adverse events in *L. loa* patients with very high MF loads (Gardon et al., 1997; Gentilini and Carme, 1981; Greene et al., 1985; WHO, 2017), which may even be aggravated by the additional microfilaricidal activity of DEC. Thus, in onchocerciasis co-endemic areas a combination of ivermectin and albendazole is used, whereas in loiasis co-endemic areas people with high microfilariae loads have to be identified and excluded from treatment, or be pre-treated with albendazole. For TPE, a 21-day treatment with 6 mg/kg DEC is recommended.

Similar to onchocerciasis, doxycycline was also shown in LF patients to be the first well-tolerated macrofilaricidal treatment that can be used as individual therapy. Four weeks of 200 mg/kg doxycycline treatment are sufficient to clear the filarial *Wolbachia* endosymbionts, which permanently inhibits filarial embryogenesis thereby clearing MF without having a direct microfilaricidal effect and slowly killing the adult worms (Debrah et al., 2011). This treatment can also be safely used against LF in patients co-infected with *L. loa* (even high) infections, since *L. loa* do not contain *Wolbachia* and are therefore not affected. It is expected that novel macrofilaricidal drugs (e.g., ABBV-4083) that are currently developed for onchocerciasis are also active against filariae causing

LF, which could help to clear remaining infections. Importantly, it is suggested that doxycycline treatment also improves lymphedema pathology, which is thought to be due to the immunomodulatory and anti-inflammatory properties of doxycycline. For the treatment of lymphedema, doxycycline should be given daily at 200 mg/kg for 6 weeks, with intervals every 12–24 months (Mand et al., 2012). In order to include this regimen into the recommendations for lymphedema management by the WHO, a multicentre study in five endemic countries (Ghana, Mali, Sri Lanka, India and Tanzania) is currently ongoing to evaluate the efficacy of doxycycline treatment (<https://doi.org/10.1186/ISRCTN14042737>) (Horton et al., 2020). The current basic standard care for lymphedema consists of hygiene measurements involving the washing of the affected limbs with soap and water, the use of topical antibiotics and antifungals and wearing shoes, to reduce bacterial and fungal infections which otherwise promote the progression of lymphedema (Dreyer et al., 2002). For large hydroceles, surgery is the only option (Betts et al., 2020; Johnson and King, 2019).

A summary of the key facts for LF covered in this chapter is presented in Table 1.

Loiasis

Short overview

Loiasis is caused by the filarial nematode *L. loa*, commonly known as “eye worm”, and is restricted to tropical rain forest areas in Central and West Africa (Benin to Gabon). In contrast to onchocerciasis and LF, loiasis has not yet been listed as NTD. It is however considered of public health relevance on its own, and because ivermectin or DEC treatment during MDA programmes against onchocerciasis and LF revealed severe adverse events including encephalitis in co-infected individuals with high *L. loa* MF loads, MDA programmes in co-endemic regions in sub-Saharan Africa are hindered.

Biology/Etiology

As shown in Fig. 1, loiasis is caused by the tissue-dwelling nematode *L. loa* that is transmitted through a bite of infected *Chrysops silacea* and *C. dimidiata* flies (Padgett and Jacobsen, 2008; Wanji et al., 2002). These flies have a diurnal biting behavior and transmit L3 during a blood meal into the bite wound. L3 migrate through the subcutaneous tissue and mature to adult female (40–70 mm in length and 0.5 mm wide) and male worms (30–34 mm in length and 0.35–0.43 mm wide). Gravid female worms release sheathed MF (250–300 µm in length and 6–8 µm wide) that can be recovered in peripheral blood, spinal fluid, urine, lung and even sputum. During another blood meal, *Chrysops* flies ingest the MF, which lose their sheaths and migrate from the midgut into the thoracic muscles of the arthropod. The L1 develop to L3 which migrate to the proboscis of the fly to get transmitted during another blood meal (Padgett and Jacobsen, 2008; Wanji et al., 2002; Zoure et al., 2011).

Epidemiology

L. loa infections are restricted to the rainforest and some savannah areas of 11 Western and Central African countries, namely Angola, Cameroon, Central African Republic, Chad, Congo, Democratic Republic of the Congo, Equatorial Guinea, Ethiopia, Gabon, Nigeria and Sudan. Approximately 14.4 million people live in high risk areas where a history of “eye worm” is present in more than 40% of individuals and 15.2 million people live in intermediate risk areas with an estimated loiasis prevalence of 20–40% (Zoure et al., 2011). *Chrysops* flies are more common during the rainy season and usually bite during the day and are attracted by the movement of people as well as smoke from fire (Noireau et al., 1990). Besides the rainforest, *Chrysops* are also prevalent in rubber plantations, palm oil groves and fringes of mangrove swamps, where they can transmit the disease (Davey and O'Rourke, 1951). Transmission of *L. loa* depends on infected vector abundance, time of exposure and number of bites.

Pathology

Due to the migration of adult worms the common clinical symptoms of loiasis are oedemas, Calabar swelling (transient subcutaneous swelling marking the migratory course of the parasite) (Fig. 7A), pruritis, arthralgia and eye worm (Fig. 7B), although the majority of infected individuals remain asymptomatic (Boussinesq, 2006; Lukiana et al., 2006). However, reports about serious adverse events including fatal cases of encephalopathy after ivermectin or DEC administration raised attention to the disease (Carme et al., 1991; Duke, 2003; Nieves-Moreno et al., 2017; Twum-Danso and Meredith, 2003). It has been shown that serious adverse events are associated with high MF loads (>30,000 MF/mL) in the peripheral blood and the inflammatory responses to the dying MF are associated with serious adverse events (Boussinesq et al., 1998, 2001; Gardon et al., 1997) causing wide-spread concern on the sustainability of community-directed treatment strategies applied for onchocerciasis and LF elimination programmes (Addiss, 2010; Amazigo et al., 2002).

Immunology and immunomodulation

Knowledge about the *L. loa*-driven immunology is limited to few studies in humans and experimental infections in mandrills, rhesus monkeys and recently developed mouse models. Those studies revealed that non-specific polyclonal IgE and elevated levels of antigen-specific IgG4 are associated with *L. loa* infection (Akue et al., 1994, 1996; Njambe Priso et al., 2018; Pinder et al., 1994) as well as distinct cytokine and chemokine patterns, especially Th1 and Th2 immune responses and eosinophil-associated cytokines (Baize et al., 1997; Chunda et al., 2020; Herrick et al., 2015; Leroy et al., 1997; Tendongfor et al., 2012).

Fig. 7 Clinical pictures caused by migrating adult *Loa loa* worms. (A) Calabar swelling and (B) eye worm.

Diagnosis

A history of Calabar swellings, which are caused by immune responses to the subcutaneous migration of the adult *L. loa* filariae, or their passage through the eye are indications of loiasis. Symptoms that can be mistaken with Calabar swellings are lesions induced by *M. perstans* or skin reactions to migrating larvae of *Strongyloides stercoralis* or hookworms from dogs or cats. The primary parasitological diagnosis is the detection of MF from the peripheral blood, although MF-negative infections, especially in patients with clinical symptoms, do exist (Dupont et al., 1988). Antigen detection tests, such as with *W. bancrofti*, are not available. Since *L. loa* MF are diurnal, blood should be taken for MF analysis during noon. Similar to the microscopic analysis of MF from *W. bancrofti* and *Brugia* species, Knott or filtration concentration methods can be used to increase the sensitivity to detect MF. Furthermore, microscopic analysis requires the differentiation of *L. loa* MF from MF of other filarial species based on morphological characteristics such as the presence of a sheath and the species-specific arrangement of the nuclei. Since a “test and not-treat” strategy is implemented in areas co-endemic for onchocerciasis (Kamgno et al., 2017), the LoaScope, a cell phone based method detecting moving MF in a fresh blood smear, was developed to identify *L. loa* patients with high MF counts that have an increased risk for severe adverse events following ivermectin treatment (Pion et al., 2020). Molecular tests to identify *L. loa* in peripheral blood and *Chrysops* flies using PCR and LAMP techniques have been established (Amambo et al., 2021; Drame et al., 2014; Fink et al., 2011). Previous serological tests were limited due to their cross-reactivity to other filarial species (Akue et al., 1996), but recent serological tests showed an increased sensitivity and specificity (Gobbi et al., 2020; Pedram et al., 2017). However, serological tests are not able to differentiate between active infections and previous exposures/infections.

Intervention/Therapy

Adverse events following drug treatment in loiasis patients is related to the MF count (summarized in Gobbi et al., 2018). DEC given at 5–10 mg/kg daily for 2–4 weeks is the standard treatment that quickly clears microfilaremia and has some macrofilaricidal efficacy. Most common adverse events following DEC treatment include fever, nausea and itching. A single oral treatment with ivermectin (200 mg/kg) also reliably clears microfilaremia, but harbors the risk of causing life-threatening serious adverse events in patients with high MF loads (as would DEC). To avoid those serious adverse events consisting of neurological symptoms, encephalopathy, coma and death, patients with more than 20,000 MF/mL blood should not be treated with ivermectin. Those patients with high MF loads can be treated twice daily with 200 mg albendazole for a total of 21 days, which has only a minor microfilaricidal efficacy and leads to a well-tolerated slow decline in MF levels (Klion et al., 1993). The risk of serious adverse events following ivermectin treatment presents a challenge for onchocerciasis elimination programs in central Africa, as it requires test-and-not-treat measurements in *O. volvulus* and *L. loa* co-endemic areas (Pion et al., 2020). However, MDA activities continue in *L. loa*

co-endemic areas, as the Mectizan Expert Committee/Technical Consultative Committee (MEC/TCC) based their recommendations on the health benefits of preventing blindness due to onchocerciasis rather than the risk of *L. loa* encephalopathy following ivermectin MDA (The Mectizan Expert Committee and The Technical Consultative Committee, 2004). Given that *L. loa* does not harbor endosymbiotic *Wolbachia* bacteria (Büttner et al., 2003; Desjardins et al., 2013; Hoerauf et al., 2008), treatments with anti-wolbachials such as doxycycline are no option.

A summary of the key facts for loiasis covered in this chapter is presented in Table 1.

Mansonellosis

Short overview

Based on the worldwide distribution of mansonellosis, but the limited knowledge about the epidemiology, biology and immunology accompanied with the lack of a distinct clinical picture of the disease, mansonellosis can be considered as the most neglected human filarial infection.

Biology/Etiology

Mansonellosis is caused by four *Mansonella* species, named *Mansonella perstans*, *M. ozzardi*, *M. streptocerca* and a newly discovered molecular clade of *M. perstans* named *Mansonella* sp. “DEUX” (Mourembou et al., 2015; Simonsen et al., 2011). Moreover, zoonotic species like *M. rodhaini* and unidentified *Mansonella* sp. have been described, but until now knowledge about mansonellosis is mainly based on *M. perstans*. Thus, transmission of *M. perstans* was associated with *Culicoides* midges (Mediannikov and Ranque, 2018; Simonsen et al., 2011; Ta-Tang et al., 2018) and recently a study in Cameroon revealed the night-biting *C. milnei* transmitting *M. perstans* in equatorial rainforest areas in Cameroon (Wanji et al., 2019). In addition, *M. streptocerca* and *M. ozzardi* are also transmitted by *Culicoides* midges, but studies also revealed that blackflies from the genus *Simulium* and non-*Culicoides* Ceratopogonidae biting midges transmit *M. ozzardi* in South America and Haiti (Crosskey, 1990; Linley et al., 1983; Shelley and Coscarón, 2001). During a blood meal, an infected arthropod transmits L3 onto the skin of the human host where they penetrate into the bite wound. Then, they develop into adult worms. *M. perstans* female (70–80 mm in length and 120 µm wide) and male (45 mm long and 60 µm wide) reside in body cavities like peritoneum, pleura and pericardium, whereas the smaller *M. ozzardi* adult worms (female: 32–61 mm long and 130–150 µm wide; male 24–28 mm long and 70–80 µm wide) reside in subcutaneous tissue that are comparable in size to *M. streptocerca* adult worms. Gravid female worms produce unsheathed subperiodic MF (MF are present at all times but reach a peak at distinct time points; *M. perstans*: 200 µm long and 4.5 µm wide) and non-periodic MF (*M. ozzardi*: 207–232 µm long and 3–4 µm wide and *M. streptocerca*: 180–240 µm long and 3–5 µm wide) that reach the peripheral blood and skin (Fig. 8). MF can be taken up during another blood meal of the vector where they migrate from the midgut into the thoracic muscles and develop from L1 to L3 that can be transmitted again to the human host (Lima et al., 2016; Mediannikov and Ranque, 2018; Orihel and Eberhard, 1982; Simonsen et al., 2011; Ta-Tang et al., 2018). An overview of the life cycle of *Mansonella* spp. is shown in Fig. 1.

Epidemiology

It is estimated that 114 million individuals are infected with *M. perstans* in West, East, and Central Africa, and in some neotropical regions of Central and South America, and that 600 million people live at high risk in 33 African countries. *M. ozzardi* is found in Central America, Argentina, Bolivia, Brazil, Colombia, Guyana, Suriname and Venezuela and several Caribbean islands. *M. streptocerca* is only prevalent in tropical regions of West, Central and East Africa. Recently *Mansonella* sp. “DEUX” have been determined in the Gabonese population (Mediannikov and Ranque, 2018; Mourembou et al., 2015; Sandri et al., 2021; Simonsen et al., 2011; Ta-Tang et al., 2018), but it remains unclear if *Mansonella* sp. “DEUX” corresponds to other zoonotic *Mansonella* species. Transmission of mansonellosis is strongly associated to distribution, abundance and seasonal occurrence of the vectors, which depends on the availability of aquatic or semi-aquatic habitats (e.g., mud or moist soil close to streams, ponds and marshes), dung of various animals, rotting fruit, cacti, banana stems and leaf detritus that serve as breeding site and are essential for the development of immature stages (Meiswinkel et al., 2004; Mellor et al., 2000; Wanji et al., 2019).

Pathology

Interestingly, mansonellosis is not associated with distinct severe clinical symptoms and thus often not considered as a public health problem. Nevertheless, there are clinical reports that associate symptoms to *Mansonella* spp. infection, including eosinophilia, subcutaneous swellings, pericarditis and pleuritis, keratitis, urticaria, arthralgia, pain or ache in bursae, joint synovia, serous cavities and liver region, fatigue and skin rashes accompanied with itching (Asio et al., 2009; Downes and Jacobsen, 2010; Fischer et al., 1999; Hoerauf, 2009; Mediannikov and Ranque, 2018; Simonsen et al., 2011; Ta-Tang et al., 2018).

Immunology and immunomodulation

The absence of distinct clinical conditions and the lack of animal infection models has resulted in a shortfall about mansonellosis immunology and immunomodulation. However, recently a study showed that *M. perstans* strongly modulates the host immune responses by dampening systemic cytokine and chemokine secretion accompanied with increased Th2 and regulatory B and T cell subsets (Ritter et al., 2018). This systematic modulation might explain the increased susceptibility and worsened disease course of tuberculosis, HIV and malaria as well as the impaired vaccination efficacy of Calmette-Guerin vaccination against tuberculosis (Elliott et al., 2010; Hillier et al., 2008; Mhimbira et al., 2017; Muhangi et al., 2007; Stensgaard et al., 2016) and suggests mansonellosis as public health concern as well as the implementation of treatment strategies against this neglected filarial nematode.

Fig. 8 Microfilariae of *Mansonella* spp. (A) Giemsa staining of *M. perstans* and hematoxylin staining of (B) *M. ozzardi* and (C) *M. streptocerca* microfilariae.

Diagnosis

Clinical indications for *Mansonella* infections are the development of pruritus, rash and dermatitis as well as eosinophilia and high IgG4 levels. As the adult worms reside in the serous cavities (*M. perstans* and *M. ozzardi*) or dermis (*M. streptocerca*), they are rarely detected. Diagnosis of *Mansonella* infections is usually based on the microscopic detection of MF in blood (*M. perstans* and *M. ozzardi*) or skin (*M. streptocerca* and *M. ozzardi*). Blood concentration techniques (Knott's or filtration technique) can be used for *M. perstans* and *M. ozzardi*, and collection of skin snips for *M. streptocerca* and *M. ozzardi* are analog to the procedure used for *O. volvulus*. In contrast to *W. bancrofti*, *Brugia* spec. and *L. loa*, MF of all three *Mansonella* species do not have a periodicity and are unsheathed. Another characteristic of *Mansonella* MF is their smaller size and in case of *M. streptocerca* MF the shepherd's crook' tail (Orihel, 1984). While serological tests are not yet available for *Mansonella* infections, PCR tests to detect MF DNA for all three species (Drame et al., 2016; Fischer et al., 1998; Morales-Hojas et al., 2001) and LAMP assays specific for *M. perstans* and *M. ozzardi* detection in peripheral blood and *Culicoides* midges do exist (Poole et al., 2019).

Intervention/Therapy

Treatment and treatment success differs among the three *Mansonella* species. Single combination treatment of ivermectin and albendazole has little to no effect on *M. perstans* microfilaremia (Asio et al., 2009; Wanji et al., 2016) and therefore *M. perstans* transmission is not interrupted by the current MDA treatments for onchocerciasis or LF. Extended treatments with DEC (200 mg twice daily) or albendazole (100 mg twice daily) alone for 21 and 28 days, respectively, reduces the MF load, and combination treatment further enhances MF clearance (Bregani et al., 2006). *Wolbachia* are present in *M. perstans* from West and Central Africa (potentially also from East Africa) and clinical trials demonstrated that daily 200 mg doxycycline treatment for 6 weeks clears microfilaremia (Batsa Debrah et al., 2019; Coulibaly et al., 2009).

For *M. streptocerca*, a 21-day treatment with DEC (2–6 g/kg body weight) was shown to eliminate both adult filariae as well as microfilariae. This treatment can cause severe pruritus and urticaria, but severe adverse events such as vision loss in onchocerciasis were not reported (Meyers et al., 1972, 1978). Similar adverse events occur following a single treatment with 150 mg/kg ivermectin, which leads to a long-lasting reduction of the *M. streptocerca* MF load (Fischer et al., 1997a).

In contrast, *M. ozzardi* MF are not susceptible for DEC treatment, but a single dose of ivermectin (150 µg/kg) mediates a maintained reduction of MF counts (Ferreira et al., 2021). As *M. ozzardi* harbors endosymbiotic *Wolbachia* bacteria (Casiraghi et al., 2001), it can be expected that doxycycline can be used as therapy.

A summary of the key facts for mansonellosis covered in this chapter is presented in Table 1.

Table 1 Summary of the key facts about the filariae *Onchocerca volvulus*, *Wuchereria bancrofti*, *Brugia spp.*, *Loa loa* and *Mansonella spp.*

<i>Filarial species</i>	<i>Endemic areas</i>	<i>Estimated infections</i>	<i>Major forms of pathology</i>	<i>Microfilariae characteristics</i>	<i>Residency of adult worms</i>	<i>Presence of Wolbachia</i>	<i>Treatment</i>	<i>Vector</i>
<i>Onchocerca volvulus</i>	Sub-Saharan Africa, Yemen, foci in Latin America	21 million	Blindness, dermatitis, Sowda	Skin, unsheathed	Subcutaneous nodules	Yes	Ivermectin, Doxycycline	<i>Simulium</i> blackflies
<i>Wuchereria bancrofti</i>	Sub-Saharan Africa, South & Southeast Asia, the Americas, Middle East, Pacific Islands	59 million	Lymphangitis, elephantiasis, hydrocele	Blood, nocturnal, sheathed	Lymphatic vessels and lymph nodes; Scrotum of men	Yes	DEC, Doxycycline, Albendazole, Ivermectin	<i>Aedes</i> , <i>Anopheles</i> , <i>Culex</i> , <i>Mansonia</i> mosquitoes
<i>Brugia malayi</i>	India, SE-Asia	6 million	Lymphangitis, elephantiasis	Blood, nocturnal, sheathed	Lymphatic vessels and lymph nodes	Yes	DEC, Doxycycline, Albendazole, Ivermectin	<i>Mansonia</i> , <i>Anopheles</i> mosquitoes
<i>Brugia timori</i>	Eastern Indonesia	?	Lymphangitis, elephantiasis	Blood, nocturnal, sheathed	Lymphatic vessels and lymph nodes	Yes	DEC, Doxycycline, Albendazole, Ivermectin	<i>Anopheles barbirostris</i> mosquitoes
<i>Loa loa</i>	Western and Central Africa	3–13 million	Eye worm, Calabar swelling	Blood, diurnal, sheathed	Subcutaneous tissue	No	DEC, Albendazole	<i>Chrysops</i> flies
<i>Mansonella perstans</i>	Sub-Saharan Africa, Central and South America	114 million	Mainly asymptomatic	Blood, unsheathed	Serous cavities	Yes	DEC, Albendazole, Doxycycline	<i>Culicoides</i> midges
<i>Mansonella streptocerca</i>	West and Central Africa	?	Mild dermatitis (mainly following treatment)	Skin, unsheathed	Dermal skin layer	Not yet verified	DEC, Ivermectin	<i>Culicoides</i> midges
<i>Mansonella ozzardi</i>	Central and South America and the Caribbean	?	Mainly asymptomatic	Blood and skin, unsheathed	Serous cavities	Yes	Ivermectin, Doxycycline?	<i>Culicoides</i> midges, <i>Simulium amazonicum</i>
<i>Mansonella Spec. "DEUX"</i>	Gabon	?	Mainly asymptomatic	Blood, unsheathed	Serous cavities	Yes	DEC?, Albendazole?, Doxycycline?	<i>Culicoides</i> ?

Acknowledgments

We are grateful to the late Dietrich W. Büttner, formerly Bernhard Nocht Institute (BNI) for Tropical Medicine, Hamburg, Germany, for agreeing to use clinical images of filariasis. Moreover, we thank Marianne Koschel from the Institute for Medical Microbiology, Immunology and Parasitology (IMMIP) for the help to illustrate the filariae shown in Fig. 1. We also thank the German Research Foundation (Deutsche Forschungsgemeinschaft – DFG) [grants RI 3036/1-1, HO 2009/10-1, HO 2009/11-1, HO 2009/14-1, LA 2746/1-2, LA 2746/2-1, and HU-2144/3-1] and the German Federal Ministry of Education and Research (Bundesministerium für Bildung und Forschung - BMBF) [grant 01KA1611 and 01KA2027] for funding of German-African collaborative projects.

Introduction

The term Leishmaniasis refers to a broad range of clinical diseases caused by different obligate intracellular protozoan parasites of the genus *Leishmania* transmitted by phlebotomine sand flies.

Traditionally, according to the geographical distribution the *Leishmania* infections are indicated as Old World leishmaniasis and New World leishmaniasis defined by different clinical presentation due to the tissue tropisms of the species involved as well as the immune status of the host (Akhoundi et al., 2016; Mejia, 2018). At least five different clinical forms can be recognized: cutaneous leishmaniasis (CL), diffuse cutaneous leishmaniasis (DCL), mucocutaneous leishmaniasis (MCL), post-kala-azar leishmaniasis (PKDL) and visceral leishmaniasis (VL).

Historic perspective

Records of cutaneous lesions that can be assimilated to the actual description of CL of the Old World dates back some 4500 years ago with typical ulcers localized on the face reported in the tablets of the court of King Ashurbanipal (650 BCE) (Manson-Bahr, 1996; Akhoundi et al., 2016; Steverding, 2017). However, no other references are recorded until Avicenna (10th century AD) described the Balkh sore in people living in the actual northern Afghanistan. On the other hand, old ceramics (4th to 9th century AD) of human figures (called huacos) from Peru and Ecuador shows face disfigurements compatible with MCL of the New World (Lainson, 1996). In the middle of 19th century Dr. Russell detailed the clinical description of “Aleppo evil” (oriental sore) and Professor Julian Bravo suggested the similarity with the Peruvian “uta” (Manson-Bahr, 1996; Lainson, 1996).

As far as VL, it is more difficult to find ancient accurate descriptions considering the wide etiologies of fever in the tropics until the outbreak of fever reported during the year 1824 in Jessore (Bengal) that was unresponsive to quinine therapy and characterized by anemia and severe cachexia (Manson-Bahr, 1996). In 1862 a similar disease was observed in Burdwan where it was responsible of a huge number of deaths and became known as “Burdwan fever” or “kala azar” (Manson-Bahr, 1996). A disease affecting mainly young children and causing anemia and splenomegaly was described in Italy in 1880 by Antonio Cardarelli and it was identified for many years (until it was recognized as Mediterranean kala-azar) as “anemia splenica infantile.”

The first accurate description of the causative agent of CL as a protozoan is by a Russian military surgeon, Pjotr Fokich Borowsky (1863–1932) who reported in 1898 the presence of the parasites in patients affected by “Sart sore” (Hoare, 1938; Manson-Bahr, 1996). However, since its discovery was published in a Russian journal it was overlooked at his time and 5 years later James Homer Wright (1869–1928) a pathologist from Massachusetts General Hospital (Boston), described and illustrated the protozoan responsible of “Delhi boil” and named it *Helicosoma tropicum* (Wright, 1903; Wyers, 2016). In the same year (1903), William

Boog Leishman (1865–1926) a Scottish army pathologist published in the *British Medical Journal* his observation made 3 year previous of “small round or oval bodies, 2–3 μm of diameter” in the spleen of a soldier who died of “Dum Dum fever” (Leishman, 1903; Wyers, 2016). However, he initially misinterpreted his findings as “degenerated trypanosomes” and raised the possibility that trypanosomiasis occurred also in India. Two months later following the article by Leishman, Charles Donovan (1863–1951) an Irish physician working at Madras Medical College in India published his post-mortem observations of similar bodies found in the spleen of three consecutive patients (Donovan, 1903; Cook, 2007). Donovan sent his slides to both the future awarded Nobel Prize Ronald Ross and Alphonse Laveran who gave different interpretation: the latter being convinced that the organisms were members of Piroplasmida (Gibson, 1983). Ross on the contrary correctly interpreted the bodies as belonging to a new genus of Sporozoa that he named *Leishmania* in honor of the discoverer and the forms observed in the spleen were referred as Leishman-Donovan bodies (Ross, 1903, 1904). In 1904 Leonard Rogers (1868–1962) was able to culture the parasite and showed under certain circumstances the appearance of a flagellate phase (resembling a trypanosome but without the undulating membrane) which suggested the possibility of a vectorial transmission (Rogers, 1904; Scott, 1939). The role of the sand fly as the possible vector of kala-azar initially suggested by Mackie should be ascribed to the epidemiological and entomological work conducted at the Calcutta School of Medicine during the years 1924–26 by Robert Knowles, LE Napier and RO Smith (Mackie, 1914; Knowles et al., 1924; Napier, 1926) which finally culminated, 16 years later, in the proof of transmission by Swaminath et al. (1942).

The parasite

The genus *Leishmania* (Ross, 1903) belongs to the Kingdom Protozoa, Infrakingdom Excavata, Phylum Euglenozoa, Class Kinetoplastea, Order Trypanosomatida, Family Trypanosomatidae (Mauricio, 2018). According to the proposed classification based on molecular data *Leishmania* species are divided into two major phylogenetic lineages: *Euleishmania* and *Paraleishmania* (Cupolillo et al., 2000; Akhoundi et al., 2016, 2017). Within the *Euleishmania* lineage there are four subgenera: *Leishmania*, *Viannia*, *Sauroleishmania* and *Mundinia* whereas the *Paraleishmania* lineage includes two subgenera: *Porcisia* (proposed to include the neotropical porcupine parasites) and *Endotrypanum*. At least 54 *Leishmania* species (without synonyms) are actually known 21 of which are able to infect humans (Maroli et al., 2012; Akhoundi et al., 2017; Cotton, 2017) (Table 1). The widespread use of different molecular typing has been responsible of the identification of several described species as synonymous: *L. infantum* (syn. *L. chagasi*), *L. donovani* (syn. *L. archibaldi*), *L. tropica* (syn. *L. killicki*), *L. mexicana* (syn. *L. pifanoi*), *L. amazonensis* (syn. *L. garnhami*) (Schonian et al., 2001, 2010; Mauricio et al., 2000; Kuhls et al., 2011). *Leishmania* are dimorphic protozoa with two distinct morphology: the amastigote (round to oval of 1.5–3 μm $\times$ 3–5 μm) found in the mammalian cells and the promastigote (elongate and flagellated form, 1.5–3.5 μm $\times$ 15–200 μm) present within the digestive tract and proboscis of the sand fly. The amastigote multiply by binary division eventually rupturing the macrophage and invading other mononuclear phagocytes. It contains a specialized mitochondrial structure that is known as kinetoplast. The promastigote possess a flagellum positioned at the anterior end of the body responsible of the movement of the parasite in the environment (Bates, 2008).

The vectors and reservoirs

Leishmaniasis is a vector-borne disease transmitted to humans by the female sand fly that belongs to the genera *Phlebotomus* in the Old World and *Lutzomyia* in the New World (Kamhawi, 2007). There are about 100 phlebotomine species identified as proven or suspected vectors of leishmaniasis (Maroli et al., 2012). The sand flies are 2–3 mm long arthropods which characteristically, in the rest position, maintain the wings at an angle to the abdomen (V configuration) (Killick-Kendric, 1999). They had limited fly capacity with hopping movement in short distance (no more than 1 m); once infected sand flies are capable of infection transmission seven to 10 days later and remain infective throughout their adult life (Dvorak et al., 2018). Phlebotomine vectors interacts with their reservoir hosts as well as the environment in a complex way that is responsible of the survival of *Leishmania* parasites (Bourdeau et al., 2020). A zoonotic transmission occurs either in domestic cycles (with the dog as the major reservoir) or in sylvatic cycles (Americas and Central Asia) where enzootic transmission between wild animals and humans (who acts as dead end hosts) is observed (Bern et al., 2008). Anthroponotic transmission (sand fly-human-sand fly) with humans as the main reservoir (Indian subcontinent and East Africa) is particularly involved for *L. donovani*. However, in East Africa it is supposed that also gerbils, rats, other rodents, small carnivores and also dogs can act as reservoir of the infection (Ashford, 1996; Sadlova et al., 2019).

In the Mediterranean basin *L. infantum* is responsible of VL and CL with nine proven or potential *Phlebotomus* vectors of the subgenus *Larrousius*: *P. perniciosus* (distributed in all countries of the Mediterranean basin), *P. ariasi* (found in Portugal, Spain, France, Italy and from Morocco to Tunisia), *P. perfiliewi*, *P. neglectus*, *P. tobbi* (identified in Italy, Greece and the Balkan peninsula), *P. longicuspis* (North Africa and Spain), *P. langeroni* (Egypt, North Africa, Spain). Dogs are highly susceptible to *L. infantum* and are considered the main reservoir but other wild canids (red foxes, jackals and wolves) can contribute to maintain the infection in nature (Lainson et al., 1969; Ashford, 1996; Dipineto et al., 2007). However, as illustrated by the “Fuenlabrada outbreak” observed between 2009 and 2013 in the Southwestern Madrid region, hares emerged as the predominant reservoir suggesting the existence of a complex rural/sylvatic transmission cycle (Molina et al., 2012; Jimenez et al., 2014). Moreover, in the Mediterranean Basin, apart the dogs the feline population remains the most affected by leishmaniosis and their possible role as primary and/or secondary reservoir hosts is increasingly considered (Asfaram et al., 2019; Cardoso et al., 2021).

Table 1 *Leishmania* species affecting humans, geographic distribution, vectors and clinical diseases.

Life cycle

Following a blood meal on an infected vertebrate, ingested *Leishmania* amastigotes will transform within the abdominal midgut of the sand fly into procyclic promastigotes (with short flagella) and, after the disintegration of the peritrophic matrix that surround and protect it, they develop into nectomonads that bind through the flagella to the microvilli of the midgut wall. Once attached these parasite forms (now leptomonads) replicate and migrate into the thoracic midgut that will be obstructed by the parasite mass embedded in the gel produced by promastigotes itself (Rogers et al., 2002). The next stage is the formation of highly motile metacyclic promastigotes (the infective stage) that concentrate in the anterior part of the midgut and sometimes in the pharynx, proboscis and salivary glands of the sand fly (Killick-Kendric, 1999; Rogers et al., 2002; Dvorak et al., 2018). It is estimated that the time needed for *Leishmania* parasites to complete the development in the sand fly is approximately 6–9 days. The mode of transmission of metacyclic promastigotes is believed to be by either deposition into the skin during feeding or blood regurgitation from the midgut (Bates, 2007, 2008).

Non-vectorial transmission

Besides the classic vector-borne transmission, leishmaniasis can be transmitted, although rarely, with blood through blood transfusion or shared syringes by intravenous drug users and following organ transplantation (Campino et al., 1994; Singh et al., 1996; Cruz et al., 2002a,b; Singh and Sivakumar, 2004; Dey and Singh, 2006; Antinori et al., 2007a,b; Mestra et al., 2011; Jimenez-Marco et al., 2016). A systematic review and meta-analysis of prevalence of *Leishmania* infection among blood donors showed, using molecular tests, a pooled prevalence of 2% with the highest prevalence in Spain (7%) and the lowest in Iran (0.05%) (Asfaram et al., 2017). Congenital transmission has been rarely reported with few well documented cases outside endemic areas (Eltoum et al., 1992; Meinecke et al., 1999; Boehme et al., 2006). Sexual transmission well demonstrated among dogs with shedding of *Leishmania* in the semen was documented in a single case in a human (Symmers, 1960; Silva et al., 2009; Naucke and Lorentz, 2012; Turchetti et al., 2014; Guedes et al., 2020).

Epidemiology

Leishmaniasis is endemic in 97 countries of which 88 are considered endemic for CL and 78 for VL in the six WHO regions (Africa, Americas, Eastern Mediterranean, Europe, South East Asia and Western Pacific) (Ruiz-Postigo et al., 2020). According to the last report of WHO in 2018, 253,435 new cases of CL (99% autochthonous) and 17,223 new VL cases (99% autochthonous) were reported (Ruiz-Postigo et al., 2020). Seven countries (Afghanistan, Algeria, Brazil, Iran, Iraq, Pakistan and the Syrian Arab Republic) report more than 70% of all CL cases; five countries (Brazil, Ethiopia, India, South Sudan and Sudan) reported more than 1000 VL cases a figure responsible of 83% of all cases worldwide.

The Global Burden of Disease Study 2013 using different sources (i.e., hospital records, national and global registries and literature) quantified for the first time the global burden of CL in 152 countries (Karimkhani et al., 2016). The highest incidence among males was observed in Palestine (616.2 per 100,000 people) followed by Afghanistan (566.4), Syria (357.1) and Nicaragua (354.8); among females, Afghanistan showed the highest incidence rates (623.9) followed by Syria (406.3), Palestine (222.1) and Nicaragua (180.8). However, CL is an emerging health problem also outside endemic regions as a consequence of war conflicts, high human mobility with migration and adventurous tourism as recognized important risk factors (Saroufim et al., 2014; Lederman et al., 2008; Sobirk et al., 2018; Kaufer et al., 2019; Vandeputte et al., 2020). Indeed, CL was diagnosed in 3.3% of travelers observed in the GeoSentinel Surveillance Network over a 10-year period (1997–2006) (Lederman et al., 2008) but imported CL is also increasingly diagnosed in endemic countries with the possible introduction of *Leishmania* species not circulating in such areas (Di Muccio et al., 2015; Ozbilgin et al., 2020). It should be highlighted that cases of imported MCL are increasingly diagnosed among young male tourists travelling in South America (especially Bolivia and Costa Rica) even after short term travel (Boggild et al., 2019).

Pathogenesis

The immune response and the pathogenesis of *Leishmania* infection is complex and not yet fully understood but the different extent of observed clinical manifestations is driven by both genetic factors of the host and the ability of the parasite to escape the innate and adaptive immune response against it. A simple model based mainly on experimental *L. major* in mice favors the description of a polarized immune response similar to what it is observed in leprosy where at one extreme of the spectrum predominate a Th2 response with polyparasitic infection (DCL and VL) and on the opposite extreme a Th1 response is responsible of a oligoparasitic infection (MCL, latent VL) (Heinzel et al., 1991; Guler et al., 1996; Launois et al., 1999; Wilson et al., 2005; Teufel et al., 2021).

However, as actually known the various contribution to susceptibility vs resistance is considered only a partial consequence of the different pleiotropic action of cytokines and their interactions with cells of the immune system (Osero et al., 2020; Carneiro et al., 2020; Teufel et al., 2021). The initial stage of the infection is characterized by recognition of parasites by macrophages, dendritic cells (DCs) and natural killer (NK) cells through pattern recognition receptors (PRRs) via Toll-like receptors (TLRs)-2,

TLR4 and TLR9. NK cells recruited by alarmins released by the damaged epithelial cells following the sand fly bite stimulates interferon-gamma (IFN- γ) production which in turn activates macrophages and up-regulates antigen processing and presentation pathways (Alexander and Brombacher, 2012; Lieke et al., 2011; Teufel et al., 2021); moreover, NK cells are able to directly kill promastigotes by lysis and their role is crucial in controlling *L. amazonensis* infection (Sanabria et al., 2008; Lieke et al., 2011). Neutrophils play, as well, a crucial role in the initial defense against *Leishmania* promastigotes by secreting neutrophil elastase (NE) which enhances the production of macrophages inflammatory cytokine and by the formation of neutrophil extracellular traps (NETs) (Kupani et al., 2021). However, neutrophils serve also as a “Trojan horse” by delayed apoptosis and intra macrophagic entry of parasites or as a “Trojan rabbit” when the parasites directly jump to macrophages without a carrier (apoptotic bodies) (Hurrell et al., 2016). Macrophages and monocytes are key cells in the defense against *Leishmania* parasites in the first hours of infection by internalization of promastigotes; within the phagolysosome of macrophages promastigotes transform in amastigotes which can replicate and destroy the macrophages causing the infection of the neighboring cells or be destroyed by killing through production of reactive oxygen species and nitric oxide through inducible nitric oxide synthase activation. (Glennie et al., 2017; Romano et al., 2017; Loria-Cervera and Andrade-Narvaez, 2020). The adaptive immune responses against *Leishmania* parasites are orchestrated by DCs through the four different cell subtypes: monocyte-derived DCs (MoDCs) and Langerhans cells (LCs) which act as antigen-presenting cells; dermal plasmacytoid DCs responsible of the synthesis of IFN- γ and dermal myeloid DCs contributing to antigen capture and presentation (Feijó et al., 2016). The interplay of different cytokines in the immunopathogenesis of *Leishmania* infection remains an unsolved paradox with the same cytokine that can be either selectively host-protective or disease-inducer according to parasite strains (Osero et al., 2020). For instance, interleukin (IL)-17A acts in synergy with IFN- γ to control *L. infantum* or *L. donovani* but on the contrary enhances the production of pro-inflammatory mediators (including IL-6 and TNF- α) in MCL caused by *L. braziliensis* and CL caused by *L. major* (Bacellar et al., 2009; Pitta et al., 2009; Terrazas et al., 2016; Gonzalez-Lombana et al., 2013). IL-12 is involved in the induction of IFN- γ that is responsible of the control of *L. major* and *L. donovani* infection but is not required for control of *L. mexicana* infection (Hurdal and Brombacher, 2017; Buxbaum et al., 2002; Engwerda et al., 1998). IL-10 produced by Th2 cells blocks directly the synthesis of Th1 cells and of IL-12 induced by macrophages impairing IFN- γ development with onset of VL and some form of CL (Anderson et al., 2007; Murphy et al., 2001; Murray et al., 2002).

Genetic studies employed with genome-wide association have been generally hampered by difficult to replicate results and by the underpower of studied population but recently robust genetic data emerged either for VL and CL resistance and susceptibility (Blackwell et al., 2009; Da Silva et al., 2020; Castellucci et al., 2020). A study by Fakiola et al. (2013) conducted in India and Brazil showed that the HLA-DRB1-HLA-DQA1 HLA class II region (rs9271858) was the single major genetic determinant of VL susceptibility (OR 1.41, 95% CI = 1.30–1.52). The studies on CL showed a more complex disease inheritance with at least six genetic risk loci identified for *L. braziliensis*: SERPINB10, CRLF3, KRT80, STX7, LAMP3 and IFNG-AS1 (Castellucci et al., 2020). Another recent study conducted in Manaus (Brazil) found that the rs2069705TT genotype was associated with a 70% risk of developing CL by *L. guyanensis* and the haplotype 1 (H1) associated with low level of IFN- γ presents a 60% risk of developing CL (Da Silva et al., 2020).

To further highlight the complex pathogenesis of leishmaniasis it should be also considered the role of *Leishmania* RNA virus (LRVs) which affects some species responsible of CL and MCL (Rossi and Fasel, 2018; Olivier and Zamboni, 2020). LRVs are members of Totiviridae, ds-RNA virus infecting a wide range of organisms with LRV1 subgenus found among New World *Leishmania* species (*L. braziliensis* and *L. guyanensis*) and LVR2 subgenus in Old World *Leishmania* (*L. major*, *L. aethiopica* and possibly *L. infantum*) (Zangger et al., 2013, 2014; Hajjarian et al., 2016). Coinfection with LRV1 and LRV2 has been associated with increased risk of developing MCL in the New World and treatment failure both in the Old and New World (Hajjarian et al., 2016; Rossi et al., 2017; Bourreau et al., 2016; Cantanhede et al., 2015).

Clinical presentation

The diagnosis of different forms of leishmaniasis (i.e., CL, MCL and VL) can be challenging because they can mimic several infectious and malignant conditions. To further complicate the picture there are atypical clinical presentations described both in immunocompetent and immunocompromised hosts (Horrillo et al., 2015; Santos-Oliveira et al., 2011; Vassallo et al., 2014; van Griensven et al., 2014a,b; Thakur et al., 2018; Neumayr et al., 2013).

Visceral leishmaniasis

The incubation period of VL ranges from as few as 10 days to as long as >1 year with a median time of 2–6 months. Asymptomatic *Leishmania* infection has been described in different geographical areas with a ratio ranging from 4 to 8.1 in the Indian subcontinent to 50:1 in Spain (Moral et al., 2002; Bern et al., 2007; Ostin et al., 2011; Singh et al., 2014). A recent study conducted in India showed that approximately 24% of asymptomatic cases (with rk-39, DAT and qPCR positivity) will develop clinical symptoms of active VL (Das et al., 2020). In such subjects high levels of Adenosine deaminase (ADA) and IL-10 were early predictors of progression from asymptomatic infection to symptomatic VL. Genetic factors (common variants in the HLA-DRB1-HLAQA1 HLA class II region), malnutrition and any conditions associated with immunosuppression contributed to the development of VL (Blackwell et al., 2009; Fakiola et al., 2013; Anstead et al., 2001).

Fig. 1 Visceral leishmaniasis with massive hepatosplenomegaly.

The presentation of VL includes the onset of fever with different clinical patterns (intermittent, remittent with double quotidian peaks or continuous), weight loss, asthenia and progressively enlarged liver and spleen (Herwaldt, 1999; Pintado et al., 2001; Cascio et al., 2002a,b; Levy et al., 2009; van Griensven and Diro, 2012). Massive splenomegaly (Fig. 1) is an important hallmark of VL and can predispose to complications such as subcapsular bleeding, infarction or even spontaneous rupture. Lymphadenopathy described in East Africa is rarely observed in the Mediterranean basin (Zijlstra and El-Hassan, 2001; Cascio et al., 2002a,b). Cutaneous papules at the site of inoculation can be observed rarely among patients with VL (Cascio et al., 2002a,b) and skin darkening (black fever or Kala-azar as indicated in Hindi language) is mainly described in South Asia.

Typical laboratory alterations in VL include anemia (almost always present) variably associated with leukopenia and thrombocytopenia as a consequence of bone marrow suppression and splenic sequestration. Impaired albumin synthesis by the liver and concomitant polyclonal hypergammaglobulinemia (5–10 g/dL) are responsible of the characteristic electrophoretic pattern known as “donkey ears” (Fig. 2). A mild-to moderate increase of liver enzymes as well as of bilirubin is frequently observed. Secondary hemophagocytic lymphohistiocytosis (HLH) associated with VL is observed especially among pediatric patients with the diagnosis complicated by the paucity of *Leishmania* amastigotes in the bone marrow or even their absence as described in 22% of cases in a study from France (Gagnaire et al., 2000; Levy et al., 2009; Minodier et al., 1998). In such cases the typical laboratory findings include hypertriglyceridemia, coagulopathy with hypofibrinogenemia and hyperferritinemia.

An atypical presentation, localized leishmanial lymphadenopathy, caused by *L. infantum*, has been recently observed among immunocompetent subjects diagnosed during the outbreak in Fuenlabrada (Spain) (Horrillo et al., 2015). This clinical entity has been rarely observed previously with only few case reports (Ignatius et al., 2011; Vera-Alvarez et al., 1999; Harms et al., 2001). A viscerotropic form caused by *L. tropica* (typically associated with CL) characterized by a milder visceral disease described among US veterans of Operation Desert Storm in Saudi Arabia, has been reported also in other regions (Iran, Kenya, Israel, India) (Magill et al., 1993; Thakur et al., 2018). Also *L. amazonensis* (in the New World) and *L. major* (in the Old World) have been reported to be responsible of VL in Bahia (Brazil) and Bushehr province (Iran), respectively (Barral et al., 1991; Karamian et al., 2007).

Undiagnosed or untreated VL progress to severe cachexia, ascites, bleeding and secondary bacterial infections responsible of death (Herwaldt, 1999; Murray et al., 2005). A scoring system based on risk factors for death developed in Brazil showed that patients with a score of 4 had a probability of death of 4.5% with a sensitivity of 89.4%, a specificity of 51.2% and an accuracy of 53.5% (Coura-Vital et al., 2014).

Visceral leishmaniasis in HIV infection

The association between VL (caused by *L. infantum*) and HIV infection was first reported in Southern Europe, mainly in Spain, France, Italy and Portugal, affecting in the majority of cases intravenous drug-users (IDU) or former IDU (Alvar et al., 1997, 2008; De la Loma et al., 1985; Vigevani et al., 1989; Monge-Maillo et al., 2014). Subsequently this coinfection has been increasingly reported in countries of Latin America and East Africa (especially Brazil, Ethiopia, Sudan, South-Sudan) where actually the burden

Serum protein electrophoresis	Results	Reference range
Albumin	25.8 %	55.8-66.1 %
α -1 globulins	4 %	2.9-4.9%
α -2 globulins	5.1 %	7.1-11.8 %
β -1 globulins	3.4 %	4.7-7.2 %
β -2 globulins	3.5 %	3.2-6.5 %
γ globulins	58.2 %	11.1-18.8 %

Fig. 2 Electrophoresis of a patient affected by visceral leishmaniasis showing the characteristic “donkey’s hear” (hypoalbuminemia and polyclonal hypergammaglobulinemia).

of the disease is highest (van Griensven et al., 2014a,b; Lindoso et al., 2014). Clinical manifestations of VL in HIV-coinfected patients mirror those observed among HIV-negative subjects (i.e., fever, weight loss, hepato-splenomegaly, pancytopenia) but several differences have also been described (Pintado et al., 2001; Romeu et al., 1991; Lopez-Velez et al., 1998; Jarvis and Lockwood, 2013). Involvement of esophagus and stomach with severe dysphagia or of the small intestine with chronic diarrhea and malabsorption or lung and pleural localization with pleural effusion or renal involvement with nephrotic/nephritic syndrome and acute renal failure are among some of the atypical manifestations described in HIV/*Leishmania* coinfection (Dattay et al., 1990; Cenoweth et al., 1993; Sollima et al., 1999; Rosenthal et al., 2000; Vassallo et al., 2014; Diro et al., 2015). Moreover, an heterogeneous number of cutaneous manifestations associated with VL occurring while the patients are still on treatment (para-kala-azar dermal leishmaniasis) or as the consequence of immune reconstitution (post-kala-azar dermal leishmaniasis-PKDL) have been described among HIV-infected patients (Ridolfo et al., 2000; Antinori et al., 2007a,b; Zijlstra, 2014). Interestingly, HIV-associated PKDL appears to be more common and more severe in this setting and caused not only by *L. donovani* but also by *L. infantum* (Ridolfo et al., 2000; Stark et al., 2006; Antinori et al., 2007a,b; Celesia et al., 2014). However, the most relevant differences regarding VL between HIV-infected and HIV-uninfected patients are about natural history and outcomes with higher mortality rates (13–18% vs 1–5%) and an high relapse rates (30–56%) observed in the former group even among patients receiving antiretroviral therapy (Antinori et al., 2007a,b; Ritmeijer et al., 2011; Sinha et al., 2011; De Araujo et al., 2012; Jarvis and Lockwood, 2013). An active chronic VL characterized by several episodes of clinical oligosymptomatic VL spared by asymptomatic periods but with the inability to clear the parasites has been described as a possible novel nosological entity in HIV-positive subjects (Bourgeois et al., 2010). A systematic review indicates that antiretroviral therapy seems to be insufficient to prevent VL-relapse with secondary prophylaxis and a CD4⁺ lymphocyte count greater than 100 cells/ μ L at the time of diagnosis as possible protective factors (Cota et al., 2011).

Visceral leishmaniasis in other immunocompromised patients

Beside HIV-positive subjects, other immunocompromised hosts such as solid organ transplant (SOT) recipients, allogenic hematopoietic stem cell recipients, rheumatologic patients treated with immunosuppressive or biologic drugs and patients with other cause of immunodeficiency are increasingly recognized as affected by VL (Antinori et al., 2008; De Leonadis et al., 2009; Boqdan, 2012; Zanger et al., 2012; Akuffo et al., 2018; Fletcher et al., 2015; van Griensven et al., 2014a,b; Komitopoulou et al., 2014; Harrador et al., 2015; Kalmi et al., 2020). SOT recipients show similar signs and symptoms of VL although splenomegaly is reported less frequently than in immunocompetent HIV-negative patients (Antinori et al., 2008). However, as observed among HIV-positive patients atypical presentation and low awareness by physicians caring for these patients may be responsible for delayed diagnosis or misdiagnosis due to overlapping symptoms and signs with other opportunistic infections (Antinori et al., 2008; Komitopoulou

et al., 2014; van Griensven et al., 2014a,b). As for HIV-positive patients, multiple relapsing course has been described, especially in kidney transplant recipients and patients treated with tumor necrosis alpha (TNF- α) antagonists (Simon et al., 2011; Bosch-Nicolau et al., 2019).

Cutaneous and mucocutaneous leishmaniasis

CL is the most frequent clinical syndrome caused by *Leishmania* infection and can present with different aspects (single or multiple lesions; localized, diffuse, disseminated lesions; dry or ulcerated lesions) according to the species involved and the host immune response (Figs. 3–5) (Goto and Lindoso, 2012; Handler et al., 2015a; Neumayr et al., 2013; Barkati et al., 2019). In the Old World, CL, known with popular name such as *Baghdad boil*, *Aleppo evil*, *bouton d'orient*, *Dehli boil*, is caused by *L. tropica*, *L. major*, *L. infantum* and *L. aethiopica*. CL is increasingly diagnosed also in non-endemic areas as the consequence of travels and population migration due to war and famine (Schwartz et al., 2006; Sharara and Kanj, 2014; Antinori et al., 2004; Wall et al., 2012; Saroufim et al., 2014; Showler and Boggild, 2015; Sobirk et al., 2018). CL can be anthroponotic (in the case of *L. tropica*) or zoonotic (when *L. major*, *L. aethiopica* and all the New World species are involved). CL caused by all *Leishmania* species presents initially with a macular lesion at the site of the vector bite that evolve over weeks into a papule or a nodule that ulcerates. The lesion does not cause pain although sometimes is responsible of itch and can heal spontaneously over several months (2–6 in the case of *L. major*; 6–15 if *L. tropica*, *L. braziliensis* or *L. panamensis* is involved) leaving a depressed hypopigmented scar (Reithinger et al., 2007; Dowlati, 1996). In the case of *L. tropica* more than 60% of affected subjects have one lesion and 95% have less than three lesions (Sang et al., 1994). Ulcerative lesions shows an oval shape with well-defined indurated borders and a central area with granulation tissue. Hyperkeratosis upon the ulcer is typical of Old World CL (Fig. 6). Sometimes a lymphangitic dissemination is observed with a lymphangitic cord detected at palpation and a “sporotrichoid” appearance (Fig. 7). Slow growing ulcers that take longer period to heal (2–5 years) are observed with *L. aethiopica*. DCL is the anergic form of CL, initially described in Africa, that can be caused by *L. aethiopica* in the Old World and by *L. amazonensis* and *L. mexicana* in the New World. After the appearance of a localized papule or nodule the disease spreads to the entire body with a predilection of the face, ears, elbows and knees resembling lepromatous leprosy (Convit et al., 1957). Systemic symptoms such as fever, weight loss, lymphedema can be present and the disease is characterized by long evolution and resistance to treatment.

Fig. 4 Old World cutaneous leishmaniasis caused by *Leishmania major* MON25.

Fig. 5 New World cutaneous leishmaniasis with several lesions localized on the face caused by *Leishmania (Viannia) panamensis*.

Fig. 6 Old World cutaneous leishmaniasis with hyperkeratotic appearance.

Fig. 7 Old World cutaneous leishmaniasis localized on the leg with sporotrichoid appearance.

Leishmania recidivans (LR) is a rare variant associated with *L. tropica* characterized by small papules (usually on the face) at the edge of a healed or healing lesion; it is a “relapsing tuberculoid form” with an intense cell mediated response and scanty parasites. LR has been observed also in the New World (Brazil and Ecuador) (Bittencourt et al., 1993; Calvopina et al., 2006).

Several forms of LCL in the New World have been described: *Chiclero’s ulcer* caused by *L. mexicana* presents with a slowly evolving ulcer usually localized on the face or pinna of the ear; *ulcera de Bejuco* is the form induced by *L. panamensis* with shallow ulcers metastatizing to lymphatic channels and with possible mucosal destruction of nasopharynx in 2–5% of patients (Koff and Rosen, 1994); *Uta*, caused by *L. peruviana*, is observed in Perú usually among children with few lesions that usually tend to heal spontaneously; CL associated with *L. braziliensis* is characterized by lymphatic spread with nodular lymphangitis (sporotrichoid distribution) and lymph node involvement (Schwartz et al., 2006). DCL is generally observed in Latin America where it was

Fig. 8 Old World mucocutaneous leishmaniasis observed in an immunocompromised host treated with Infliximab.

originally described in 1920 with *L. braziliensis* as the main species causing the disease (Torres, 1920; Turetz et al., 2002; Machado et al., 2019); however, also *L. panamensis* and *L. guyanensis* can be responsible of this tegumentary syndrome in the New World (Calvopina et al., 2005). DCL has been rarely observed also in Europe, in a patient treated with TNF- α antagonists, and in the Middle East (Neumayr et al., 2013; Alborzi et al., 2008; Alkover et al., 2018). A single case caused by *L. siamensis* has been described in a Thai patient treated with systemic steroids (Noppakun et al., 2014). DCL is defined by multiple pleomorphic lesions (more than 10, frequently hundreds to thousands) in two or more non-contiguous areas of the body; The lesions are localized on the face, the trunk and the limbs with acneiform, papular, nodular or ulcerated appearance and an high rate (>50%) of mucosal (especially of the nose) involvement (Machado et al., 2019).

MCL is traditionally caused by *L. braziliensis* in Latin America although other species (*L. amazonensis*, *L. guyanensis*, *L. panamensis*) have also been implicated (Goto and Lindoso, 2010). Although MCL can present simultaneously with cutaneous lesions it generally appears several months or years following CL. Initially symptoms are nonspecific with itching to the nose, mucosal swelling with stuffy nose, crust formation with bleeding; following the initial involvement of the nasal mucosa the disease spreads to oral mucosa, soft palate, pharynx and larynx. MCL has been observed, although rarely, also in the Old World, especially among patients treated with immunosuppressive drugs (Cobo et al., 2016; Patel et al., 2017). (Fig. 8).

Post-kala-azar dermal leishmaniasis (PKDL)

Post-kala-azar dermal leishmaniasis is a possible complication of VL caused by *L. donovani* observed mainly in Sudan and India (Zijlstra, 2014); however, in recent years cases of PKDL have been reported also in the Mediterranean basin and Latin America following infection with *L. infantum/chagasi* in HIV-positive patients (Bittencourt et al., 2002; Antinori et al., 2007a,b; Ramos et al., 2008). A difference regarding the prevalence rate, clinical presentation and time onset from the episode of VL is observed in Asia and Africa (Zijlstra, 2014; Burza et al., 2018). In Africa, PKDL develop in 50% of individuals after a short interval from the episode of VL, affects mainly children and papulo-nodular lesions predominate; in Asia, the rash is more frequently macular, symmetric and hypopigmented, the time lag is longer (2–3 years) and the prevalence rate is 5–10% (Zijlstra et al., 2003). In one study conducted in Ethiopia, PKDL was observed more frequently among HIV-positive patients in comparison with HIV-negative (27% vs 13%) and the clinical course was more severe (Rijtmeyer et al., 2006). Moreover, PKDL lesions in HIV-positive subjects contain an high parasite burden (Zijlstra, 2014).

Diagnosis of leishmaniasis

The diagnosis of the different clinical syndromes associated with *Leishmania* infection traditionally relies on the direct microscopy observation of the parasite on suitable samples (i.e., skin, bone marrow, spleen, liver, lymph node biopsies or aspirates) and/or culture (Kumar et al., 2007; Srivastava et al., 2011; Gramiccia and Di Muccio, 2018; Burza et al., 2018; Reimao et al., 2020). However, besides histopathology and *in vitro* culture the diagnostic armamentarium for leishmaniasis is actually based on several serologic and antigen detection assays and molecular tools (Cunningham et al., 2012; De Ruiter et al., 2014; Srivastava et al., 2011; Hossain et al., 2017). Molecular tests, especially polymerase chain reaction (PCR) have been increasingly used not only for diagnosis and species identification but also for post-treatment assessment of cure (Kip et al., 2015; Hossain et al., 2017). More recently, mass spectrometry has been proposed as a possible application for rapid and reliable identification of *Leishmania* species (Cassagne et al., 2014; Mouri et al., 2014; Lachaud et al., 2017).

Diagnosis of visceral leishmaniasis

The differential diagnosis of VL must take into account several infectious and non-infectious diseases characterized by febrile pancytopenia and splenomegaly. Bone marrow, spleen or less frequently lymph nodes are the main sources of samples from which microscopy examination and culture are performed (Sundar and Rai, 2002a; Srivastava et al., 2011). Spleen aspirate is characterized by the highest sensitivity (93–99%) but it is routinely done only in the Indian subcontinent and East Africa (Zijlstra et al., 1992; Sundar and Rai, 2002a); in Europe, Brazil and the United States the bone marrow is the preferred sample but its sensitivity is around 60–85% (Zijlstra et al., 1992; Siddig et al., 1988; Ho et al., 1948). Several bone marrow findings associated with VL have been described with hypercellularity being the most frequently observed (Kumar et al., 2007; Dhingra et al., 2010; Al-Jurayyan et al., 1995; Wickramasinghe et al., 1987); in such cases, the abundance of Leishman Donovan (LD) bodies is a distinct features that allow to discriminate from hematologic and storage diseases (Kumar et al., 2007). Noncaseating granuloma is another frequently observed picture among patients with VL characterized by paucity of LD bodies and need to employ PCR to obtain the correct diagnosis (Kumar et al., 2007). Ultrastructural studies showed the presence of a high proportion of immature erythroblasts with giant lysosomes suggesting a role of dyserythropoiesis in the pathogenesis of anemia (Wickramasinghe et al., 1987).

In highly endemic regions rapid diagnostic tests (RDTs) such as the direct agglutination test (DAT) and the lateral flow immunochromatographic test (ICT) are extensively used for the diagnosis of VL (Singla et al., 1993; De Assis et al., 2011; Chappuis et al., 2006; Cunningham et al., 2012; Bhattacharyya et al., 2013; Boelaert et al., 2014; van Griensven and Diro, 2019). The DAT showed a good sensitivity and specificity for the diagnosis of VL in both the Indian subcontinent and Eastern Africa with the major disadvantages being the time needed for the response (hours), the persistence of positive results even among cured subjects and a high rate of positivity among patients with asymptomatic infection (Chappuis et al., 2006). Moreover, since the test is based on whole parasite antigen in endemic areas cross-reactivity with other parasites can be a problem (Kohanteb and Ardheali, 2005). The k39 antigen that contains 39 amino acids encoded by the highly conserved kinesin region of *L. infantum*/*L. chagasi* is the basis of the ICT test widely used especially in the Indian subcontinent as a part of the kala-azar elimination program (Sundar et al., 1998; Boelaert et al., 2014; Maia et al., 2012). The rK39 tests shows a high sensitivity and specificity in study conducted in the Indian subcontinent whereas its performance is lower in East Africa and among HIV-coinfected patients (Boelaert et al., 2014; Bangert et al., 2018; Kassa et al., 2020). Although this test is considered a reliable point-of-care method, as for DAT, it is unable to discriminate between current, subclinical and past leishmania infections (Sundar and Singh, 2018). Another ICT adopting the rK28 antigen demonstrated similar high performance in the Indian Subcontinent but improved sensitivity in East Africa (Pattabhi et al., 2010; Vaish et al., 2012; Bezuneh et al., 2014; Mukhtar et al., 2018). Molecular diagnosis of VL by means of PCR can be considered a real breakthrough for the detection and typing of different *Leishmania* species (De Ruiter et al., 2014). The PCR-based approach using different primers targeting the nuclear and mitochondrial genome of the parasite (i.e., small subunit ribosomal RNA, kinetoplast DNA, multicopy mini-exon RNA) has been increasingly adopted because of several advantages in comparison with standard microbiologic methods: high sensitivity (>95%) even when peripheral blood samples are employed; rapid response; direct applicability on clinical samples not requiring the parasite cultivation; usefulness for therapeutic monitoring with low invasiveness especially in pediatric population; similar performance with *L. donovani* and *L. infantum* (Nuzum et al., 1995; Osman et al., 1997; Singh et al., 1999; Pizzuto et al., 2001; Cruz et al., 2002a,b; Cascio et al., 2002a,b; Fisa et al., 2002; Wortmann et al., 2005; Antinori et al., 2007a,b; Boelaert et al., 2014). A quantitative real-time PCR has been suggested to be useful as an early predictor of VL relapse especially among HIV-positive subjects although there is no agreement about the cycle threshold value to be used (Bossolasco et al., 2003; Mary et al., 2006; Antinori et al., 2009; Hossain et al., 2017). A further achievement in the diagnosis of VL has been the development of a loop-mediated isothermal amplification (LAMP) assay to be used especially in the field setting (Abbasi et al., 2016; Mukhtar et al., 2018; Silva Nunes Bezerra et al., 2020). For a more extensive dissertation about the molecular diagnosis of VL the readers are referred to several updated reviews (Boelaert et al., 2014; Sundar and Singh, 2018; Gramiccia and Di Muccio, 2018; van Griensven and Diro, 2019; Reimao et al., 2020). Serological diagnosis of VL has been extensively used in the past but its indirect nature and variable sensitivity and specificity together with the availability of more specific methods is responsible of their actual limited use (Sundar and Rai, 2002a,b; Aronson et al., 2016). Moreover, in the context of low endemicity or absence of the disease is not infrequent that such tests are requested when a diagnosis of VL has been obtained with a direct method. The available serological tests are based on immunofluorescence (indirect fluorescent antibody test-IFAT), enzyme linked immunosorbent assay (ELISA) and western blotting and their performance is variable and dependent to antigens used and the epidemiological setting (Gari-Toussaint et al., 1994; Kumar et al., 2001).

Diagnosis of cutaneous and mucocutaneous leishmaniasis

CL presents with lesions that can mimic several infectious (ecthyma, sporotrichosis, tuberculosis, leprosy, blastomycosis, paracoccidioidomycosis) and non-infectious (basal cell carcinoma, squamous cell carcinoma, lymphoma, sarcoidosis, pyoderma gangrenosum) disease (Handler et al., 2015b; Goto and Lindoso, 2012; Singh and Ramesh, 2013). Diagnosis should be suspected in any afebrile subjects with a history of residence or travel in a leishmaniasis-endemic area presenting with a non-healing cutaneous lesion (Aronson et al., 2016; Goto and Lindoso, 2012). Histologic examination of a sample obtained by skin scraping or by biopsy (incisional/excisional) of ulcer or nodule border is the first step to accomplish the diagnosis of CL although sensitivity is around 50–60% (Singh et al., 2014; Viana et al., 2013). Since identification of the species is of paramount importance, especially in the New World, for species-directed therapy the use of PCR is highly recommended (Aronson et al., 2016; Marfurt et al., 2003a,b; Jara et al., 2013).

MCL needs to be differentiated from syphilis, yaws, rhinoscleroma and oral squamous cell carcinoma; mucosal samples for histopathologic and molecular diagnosis are generally obtained by an otolaryngologist (Aronson et al., 2016).

Treatment

Traditionally pentavalent antimonials (sodium stibogluconate and meglumine antimoniate) have been used as the drugs of choice for the treatment of VL all over the world. However, in some endemic areas such as the state of Bihar (India) the resistance rate to pentavalent antimonials (PA) reached a 60% value which required the adoption of different therapeutic regimens (Sundar and Rai, 2002b; Hefnawy et al., 2017). Several clinical trials showed the usefulness of different drugs such as amphotericin B deoxycholate (AMB-d), pentamidine and paromomycin for the treatment of VL (Thakur et al., 1993, 2000; Sundar et al., 2007). Major breakthrough for the treatment of VL were the approval in 1997 by the Food and Drug Administration of liposomal amphotericin B (L-AMB) and in 2002 the clinical trial that conducted to the approval in India of miltefosine, the first and only oral drug with such an indication (Davidson et al., 1994; Meyerhoff, 1999; Sundar and Rai, 2002b). Since then, several randomized clinical trials have been conducted especially in India and East Africa which are elegantly summarized in two reviews (Monge-Maillo and Lopez-Velez, 2013; Berman, 2015). Up to now options for the treatment of VL include parenteral monotherapy (with L-AMB, PA, pentamidine or AMB-d) or combination therapy (PA plus paromomycin), use of high dosage of L-AMB for short course (10 mg/kg over 2 days), oral therapy with miltefosine.

PA have been used for VL for over 80 years and except in the Indian subcontinent they maintain a role as first line therapy in eastern Africa, administered either alone (20 mg Sb^{V+}/mL/kg for 30 days) or in association with paromomycin (15 mg/kg intramuscularly) for 17 days (Table 2). The two available formulations have different pentavalent antimony concentration: 100 mg Sb^{V+}/mL sodium stibogluconate and 85 mg^{V+}/mL meglumine antimoniate. Both drugs show good efficacy but the main concern is about cardiotoxicity (T-wave flattening or inversion, QT interval prolongation) and pancreatic damage; therefore an electrocardiogram and pancreatic enzyme monitoring are mandatory during treatment. AMB-d is an option used for the treatment of VL and MCL characterized by good efficacy but undermined by the need of long hospitalization and high rate of nephrotoxicity. L-AMB with a total dose of 18–21 mg/kg is currently the treatment of choice for VL in high-income countries but is adopted also in the Indian subcontinent with different schedules of administration (Table 2). Paromomycin at a dosage of 15 mg (11 mg base)/kg/day emerged as a good options for the treatment of VL caused by *L. donovani* in India; however, its efficacy as monotherapy is lower in East Africa where prolonged regimen (from 21 to 28 days) or higher dosage (20 mg (15 mg base)/kg/day) proved more effective than the regimen adopted in India. Pentamidine isethionate (4 mg/kg three times weekly for 12–21 days) was used in India when PA became less effective due to emerged resistance but its actual role is limited to secondary prophylaxis for VL in HIV/coinfected patients (Thakur, 1984; Mishra et al., 1992; Diro et al., 2019). Miltefosine is registered in India, Germany and other countries of South America for treatment of VL and CL (Monge-Maillo and Lopez-Velez, 2015) at a dosage of 2.5 mg/kg/day for children and 150 mg/day for adults for 4 weeks. Main toxicity observed for miltefosine is on the gastrointestinal tract (nausea, vomiting, diarrhea) and the possible teratogenicity that precludes its use in pregnant women.

For more exhaustive information about treatment of VL the readers should refer to guidelines of IDSA/ASTMH (Aronson et al., 2016), WHO (Gradoni et al., 2017), Organizacion Panamericana de la Salud (2013), India (National Vector Borne Disease Control Programme, 2015) and to several comprehensive reviews (Monge-Maillo and Lopez-Velez, 2013, 2015; Copeland and Aronson, 2015; van Griensven and Diro, 2012, 2019; Burza et al., 2018).

Treatment of LCL is complicated by several factors including a high number of involved species with different susceptibility to available drugs, lack of well conducted clinical trials, different host populations (immunocompromised, travelers, children) and different possible options (local treatment, systemic treatment, intralesional treatment, physical treatment). As a general rule systemic treatment is recommended for all patients with CL acquired in the New World to prevent the development of MCL (Blum et al., 2012). Moreover, other factors that need to be considered when choosing a treatment regimen for CL are the infecting *Leishmania* species, the number and size of lesions and their location (face, hands, joints) and the host immunological status (i.e., immunocompromised patients) (WHO, 2014; Hodiamont et al., 2014; Showler and Boggild, 2015; Aronson et al., 2016; Blum et al., 2018). In Table 3 (near here) are summarized the treatment options for CL according to the different *Leishmania* species involved. Disseminated cutaneous leishmaniasis (DCL) and PKDL are tegumentary form more difficult to be treated. DCL is a hard to treat syndrome generally relapsing once therapy is discontinued with options represented by the combination of paromomycin and antimonials or pentamidine isethionate (van Griensven et al., 2016); prolonged treatment with miltefosine has been reported to be successful in several case reports (Zerpa et al., 2007; Ordaz-Farias et al., 2013). For DCL caused by *L. braziliensis* a high rate of therapeutic failure up to 76% has been observed with the use of pentavalent antimony (Machado et al., 2011). More recently, the use of L-AMB with a total cumulative dose above 30 mg/kg showed a cure rate of 75% (Machado et al., 2015). PKDL is considered an obstacle of VL elimination in the Indian subcontinent and therefore it is indicated as treatment although in the majority of cases skin lesions are self-healing (Le Rutte et al., 2019; Gedda et al., 2020). Sodium stibogluconate (20 mg/kg/day for 20 days per month for 6 months) was considered the treatment of choice but it has been replaced by other drugs because of several limitations (long hospitalization needed, high toxicity) (Singh and Sivakumar, 2004). Miltefosine (100 mg/day for 12–16 weeks) is associated with high cure rates but its use is sometimes limited by gastrointestinal toxicity (Ramesh et al., 2011; Pijpers et al., 2019). L-AMB using different treatment schedules (2.5 mg/kg for 20 days in East Africa; 5 mg/kg dose twice per week for 3 weeks in the Indian subcontinent) is suggested by some expert as a first-line treatment (Gedda et al., 2020; Blum et al., 2018). In East Africa, another option is the combination of sodium stibogluconate (20 mg Sb^{V+}/kg/day) plus paromomycin (15 mg (11 mg base)/kg/day) for 17 days (Burza et al., 2018).

Table 2 Drugs and treatment schedules for visceral leishmaniasis.

Leishmania species/Geographic area	Regimen and dose	Major side effects	Comments and grade
<i>L. donovani</i> /East Africa	Sodium stibogluconate 20 mg/kg Sb ^{V+} /day i.m. or i.v. for 30 days	Cardiotoxicity, pancreatitis, hepatotoxicity	Grade A ^a Cure rate 94% (Burza et al., 2018)
	Sodium stibogluconate 20 mg/kg Sb ^{V+} /day i.m. or i.v. plus paromomycin 15 mg (11 mg base)/kg/day i.m. for 17 days	Cardiotoxicity, pancreatitis, hepatotoxicity (SSG); ototoxicity, nephrotoxicity (PM)	Grade A ^a Cure rate 91% (Burza et al., 2018)
	Liposomal amphotericin B (L-AMB) 3–5 mg/kg/day i.v. for 6–10 days (total dose 30 mg/kg)	Fever, back pain, nephrotoxicity	Grade B ^a STRONG recommendation, HIGH quality of evidence (Aronson et al., 2016) (Doses of up to 40 mg/kg may be necessary in person with VL acquired in East Africa) Cure rate >91% (Burza et al., 2018) Not recommended ^a
Coinfection HIV/ <i>L. donovani</i> /East Africa	Pentamidine isethionate 4 mg/kg/day i.v. on alternate days for 15–20 doses	Hypotension, pancreatitis, diabetes mellitus	
	L-AMB 3–5 mg/kg/day i.v. (days 1–5, 10, 17, 24, 31, 38) up to a total dose of 40 mg/kg	Fever, back pain, hypokalemia, nephrotoxicity	Cure rate 50% (Burza et al., 2018)
	L-AMB 5 mg/kg/day i.v. (days 1, 3, 5, 7, 9, 11) plus miltefosine 2.5 mg/kg/day (children) or 100 mg/day os for 28 days	Fever, back pain, hypokalemia, nephrotoxicity (L-AMB)	Not recommended ^a Cure rate 67% (Burza et al., 2018)
<i>L. donovani</i> /Indian subcontinent	L-AMB 10 mg/kg i.v. for 1 or 2 doses	Fever, back pain, hypokalemia, nephrotoxicity	Grade A ^a STRONG recommendation, HIGH quality of evidence (Aronson et al., 2016) Cure rate 96% (Burza et al., 2018)
	L-AMB 3–5 mg/kg/day i.v. for 3–5 days	Fever, back pain, hypokalemia, nephrotoxicity	
	L-AMB 5 mg/kg as a single dose plus miltefosine 150 mg/day for 7 days		Grade A ^a Cure rate 98% (Burza et al., 2018)
	AMB-d 0.75–1 mg/kg i.v. daily or on alternate days for 15–20 doses	Fever, hypokalemia, nephrotoxicity (frequent)	Grade A ^a Cure rate 93% (Burza et al., 2018)
	Miltefosine 150 mg/day os for 28 days	Gastrointestinal side effect (nausea, diarrhea, vomiting); hepatotoxicity (MF)	Grade A ^a STRONG recommendation, MODERATE quality of evidence (Aronson et al., 2016) Cure rate 90% (Burza et al., 2018)
Coinfection HIV/ <i>L. donovani</i> /Indian subcontinent	L-AMB 3–5 mg/kg i.v. for 10 doses (days 1–5, 10, 17, 24, 31, 38)	Fever, back pain, hypokalemia, nephrotoxicity (rare)	STRONG recommendation, LOW quality of evidence (Aronson et al., 2016)
	L-AMB 5 mg/kg/day i.v. for 6 days plus miltefosine 100 mg/day for 14 days os	Fever, back pain, hypokalemia, nephrotoxicity (rare) (L-AMB); Gastrointestinal side effects (nausea, diarrhea, vomiting); hepatotoxicity (MF)	WEAK recommendation, VERY LOW quality of evidence (Aronson et al., 2016)
<i>L. infantum</i> /chagasi/Mediterranean basin; Latin America	L-AMB 3–5 mg/kg/day i.v. (days 1–5, 10)	Fever, back pain, hypokalemia, nephrotoxicity (rare) (L-AMB)	Grade B ^a ; Grade C ^a (Latin America) STRONG recommendation, HIGH quality of evidence (Gradoni et al., 2017) Cure rate 90–98% (Burza et al., 2018)
	Meglumine antimoniate 20 mg Sb ^{V+} /kg/day i.m. or i.v. for 28 days	Cardiotoxicity, hepatotoxicity, pancreatitis	Grade B ^a STRONG recommendation, MODERATE quality of evidence (Gradoni et al., 2017) Cure rate 97% (Burza et al., 2018)
Coinfection HIV/ <i>L. infantum</i> /chagasi/Mediterranean basin; Latin America	L-AMB 3–5 mg/kg i.v. for 10 doses (days 1–5, 10, 17, 24, 31, 38)	Fever, back pain, hypokalemia, nephrotoxicity (rare) (L-AMB)	STRONG recommendation, VERY LOW quality of evidence (Gradoni et al., 2017) Cure rate 80% (Burza et al., 2018)
	Miltefosine 150 mg/day for 28 days os	Gastrointestinal side effects (nausea, diarrhea, vomiting); hepatotoxicity	WEAK recommendation, LOW quality of evidence (Gradoni et al., 2017)

i.v., intravenous; i.m., intramuscularly; L-AMB, liposomal amphotericin B; MF, miltefosine.

^aOxford evidence grading system: (A): randomized controlled trials in representative patient groups; (B): randomized controlled trials in less homogenous patient group; (C): cohort trials or case control studies in less homogenous patient group, as well as case series of representative patient groups; (D): case series of less homogenous patient groups and expert opinion.

Table 3 Treatment regimens suggested for cutaneous (CL) and mucocutaneous leishmaniasis (MCL).

Old World CL	Local treatment	Grade	Systemic treatment	Grade
<i>Leishmania major</i>	Cryotherapy plus intralesional antimonials	A (Burza et al., 2018); A (Blum et al., 2014)	Fluconazole 200 mg bid for 6 weeks	A (Burza et al., 2018); C (Blum et al., 2014) Fact, no grade (Aronson et al., 2016)
	15% paromomycin plus 12% methylbenzethonium chloride bid for 10–20 days	A (Burza et al., 2018); A (Blum et al., 2014)	Miltefosine 50 mg every 8 h for 4 weeks	B (Blum et al., 2014)
	Heat therapy (50 °C for 30 s): 1–2 sessions	A (Blum et al., 2014)	Pentavalent antimonials (Sb ^{v+} 20 mg/kg/day plus pentoxifylline 400 mg three times daily for 20 days)	A (Burza et al., 2018); A (Blum et al., 2014) STRONG recommendation, MODERATE quality of evidence (Aronson et al., 2016) (Systemic treatment recommended for persons with complex CL)
<i>Leishmania tropica</i> and <i>L. infantum</i>			L-AMB 3 mg/kg/day (days 1–5 and 10)	D (Blum et al., 2014)
	Pentavalent antimonials (Sbv + 20 mg/kg/day)	D (Burza et al., 2018); A (Blum et al., 2014)	Pentavalent antimonials (Sb ^{v+} 20 mg/kg/day for 10–20 days)	D (Burza et al., 2018); D (Blum et al., 2014)
	Heat therapy (50 °C for 30 s): 1–2 sessions	A (Burza et al., 2018); A (Blum et al., 2014)	L-AMB 3 mg/kg/day (days 1–5 and 10)	C (Blum et al., 2014) STRONG recommendation, MODERATE quality of evidence (Aronson et al., 2016) (Systemic treatment recommended for persons with complex CL)
	15% paromomycin plus 12% methylbenzethonium chloride bid for 10–20 days	D (Blum et al., 2014)	Miltefosine 50 mg every 8 h for 4 weeks	D (Blum et al., 2014)
			Pentavalent antimonials (Sb ^{v+} 20 mg/kg/day for 10–20 days)	C (Blum et al., 2014)
New World CL	Local treatment	Grade	Systemic treatment	Grade
<i>Leishmania braziliensis</i>	Heat therapy (50 °C for 30 s): 1–2 sessions (not from Bolivia)	A (Burza et al., 2018)	Pentavalent antimonials (Sb ^{v+} 20 mg/kg/day for 20 days)	C (Burza et al., 2018) STRONG recommendation, MODERATE quality of evidence (Aronson et al., 2016) (All species: choice of agent, dose, and duration of therapy should be individualized)
<i>Leishmania guyanensis</i>			L-AMB 3 mg/kg/day (days 1–5 and 10)	C (Burza et al., 2018)
	No data		Miltefosine 50 mg every 8 h for 4 weeks	
			Pentamidine isethionate 4 mg/kg on alternate day for 3 infusions	C (Burza et al., 2018)
<i>Leishmania mexicana</i>			Miltefosine 50 mg every 8 h for 4 weeks	C (Burza et al., 2018)
	15% paromomycin plus 12% methylbenzethonium chloride bid for 10–20 days	B (Burza et al., 2018)	Pentavalent antimonials (Sb ^{v+} 20 mg/kg/day for 10–20 days)	C (Burza et al., 2018)
			Ketoconazole 600 mg/day for 4 weeks	B (Burza et al., 2018)
<i>Leishmania panamensis</i>	Heat therapy (50 °C for 30 s): 1–2 sessions	B (Burza et al., 2018)	Miltefosine 50 mg every 8 h for 4 weeks	B (Burza et al., 2018)
	15% paromomycin plus 12% methylbenzethonium chloride bid for 10–20 days		Pentamidine isethionate 4 mg/kg on alternate day for 3 infusions	C (Burza et al., 2018)
			Pentavalent antimonials (Sb ^{v+} 20 mg/kg/day for 10–20 days)	C (Burza et al., 2018)
			Ketoconazole 600 mg/day for 4 weeks	
New World MCL	Local treatment	Grade	Systemic treatment	Grade
Any species	Not applicable		Pentavalent antimonials (Sb ^{v+} 20 mg/kg/day plus pentoxifylline 400 mg three times daily for 4 weeks)	A (Burza et al., 2018) STRONG recommendation, MODERATE quality of evidence (Aronson et al., 2016) (Drug, dose and duration therapy should be individualized)
			L-AMB 3 mg/kg/day up to 40–60 mg/kg as total dose	C (Burza et al., 2018) STRONG recommendation, MODERATE quality of evidence (Aronson et al., 2016) (Drug, dose and duration therapy should be individualized)
			Pentamidine isethionate 4 mg/kg on alternate day for 3 infusions	C (Burza et al., 2018) STRONG recommendation, MODERATE quality of evidence (Aronson et al., 2016) (Drug, dose and duration therapy should be individualized)

MCL requires the use of systemic antileishmanial therapy to prevent complications such as disfigurement and mortality (Aronson et al., 2016); PA in Latin America still stand as the treatment of choice (20 mg Sb^{V+}/kg/day for 28–30 days) alone or in combination with pentoxifylline 400 mg every 8 h for 30 days (Lessa et al., 2001; Machado et al., 2007). AMB-d at the dose of 0.5–1.0 mg/kg/daily or every other day up to a cumulative total dose of 20–45 mg/kg or L-AMB with a cumulative total dose of 20–60 mg/kg are possible alternative drug therapies (Amato et al., 2007, 2008).

Perspectives of control

Leishmanization, i.e., the practice of inoculation of live *Leishmania* parasites to prevent CL has been used for centuries in the Middle East and former Soviet Union countries with reported efficacy of near 100% (Nadim et al., 1983; Khamesipour et al., 2005; Mohebbi et al., 2019). Several first-generation vaccines (using dead parasites), second-generation vaccines (using genetically modified parasites expressing *Leishmania* genes encoding for recombinant proteins) and third-generation vaccines (plasmid-DNA-based) are currently studied to control human leishmaniasis (Pandey et al., 2020). Interestingly, the demonstration that pre-exposure to sand fly saliva confers protection against vector-transmitted leishmaniasis (Kamhawi et al., 2000; Oliveira et al., 2015) raised the possibility to develop a pan-leishmania vaccine through a reverse vaccinology approach (Cecilio et al., 2020).

Currently, a third-generation vaccine (ChAd63-KH) based on a simian adenovirus expressing a synthetic gene (KH) encoding two *Leishmania* proteins (KMP-11 and HASPB) has been evaluated in phase 1 and 2 clinical trials in humans (Osman et al., 2017; Younis et al., 2021). In this regard a recent simulation showed that a possible vaccine against leishmaniasis able to reduce infectivity towards sand flies or to reduce the risk of developing symptoms after infection can greatly reduce VL incidence on the Indian subcontinent (Le Rutte et al., 2020).

In the context of One Health approach, the practice of culling infected dogs as a measure to control the domestic reservoir of *L. infantum* and consequently reduce the risk for VL has been recommended to no longer be used (Dantas-Torres et al., 2019). Three vaccines are commercially available for canine leishmaniosis prevention (LetiFend[®], Leish-Tec[®] and CaniLeish[®]) showing different efficacy in their capacity to prevent infection (from 68.4% to 80%) but it appears difficult to make any attempt to compare their efficacy and effectiveness (Velez and Gallego, 2020).

The existence and the status of parasitic infections in living beings of the past periods of time can be demonstrated by taking advantage of parasitological investigations. The study of biological remains obtained from the archeological sites, reveals that diseases have accompanied humans and animals on the earth since their emergence, which proves that no paradise free of pathogens has existed in the world (Souza et al., 2003). Besides detecting the parasites of ancient times, paleoparasitology sheds light on many other angles for a better understanding of the lives of human ancestors. The pattern of exchanging diseases in human societies beyond the geographical territories with different cultural beliefs can be also be discussed in this line of research. Specimens for studying in paleoparasitology include soft tissues of mummies, human and animal excrement, burial soils, and many other sediment materials that may have retained many biological agents including parasite particles such as helminth eggs from the past up to the current times. The samples submitted to the laboratory of paleoparasitology are invaluable biological remains that have been preserved in archeological sites over time and should be carefully managed so that no further sampling would be necessary. Some of these materials are unique enough which are not accessible on ordinary occasions. Although all owners of these samples have been previously traveled elsewhere and or died, a wide range of biological samples is left for us around their residing areas. On occasions, food remains and animal excrements nearby humans can be found during the excavation projects that may help researchers to confirm the initial results of being investigated. Apart from the bioarcheological specimen, there are some remarkable old historical documents on parasitic infections of which the Ebers papyrus of 1500 BCE, along with more accurate descriptions of parasitic diseases by the recent Iranian physicians, Rhazes AD 850 to 923 and Avicenna 980 CE to 1037 that are more exemplary herein (Cox, 2002) are available. Based on signs and symptoms described in historical narratives, the possible role of certain parasites as causative pathological agents can be imagined in some of those known characters. This is while tracking to find the mentioned individual's samples would not be possible for the most heard scenarios. There are some pathognomonic clinical manifestations that are appeared in fiction that declare public awareness concerning certain diseases in the far past. The "devil snake" that Iranian poet Abul-Qâsem Ferdowsi Tusi mentions as the legend of "Zahhak the Snake Shoulder" in Shahnameh (Book of Kings 977–1010 CE), and the metaphor "the disease of Reshteh" by Saadi Shīrāzī in (1210 CE), are both presumably referring to *Dracunculus medinensis* "Little Dragon of Medina" or "fiery serpent" that has also been described in the Bible.

Since the recovery of *Schistosoma haematobium* eggs in an Egyptian mummy by Ruffer (1910) various perspectives have been put forward to describe the importance of paleoparasitological findings, like what is stated in "Foundations of Paleoparasitology" by the pioneers, Luiz Fernando Ferreira, Karl Jan Reinhard, and Aduino Araujo. In this new emerging line of research, many historical events can also be tracked and re-documented. Finding a parasite at a specific time in a geographical region indicates the establishment of that life cycle and the presence of its various related biotic and abiotic elements. Information like the route of ancient human migration on the earth, predominant diets among human beings as well as lifestyles and behaviors could be indicated by the identification of a specific parasite. In studying the parasite of ancient times, coprolites are known as the most valuable enriched specimens of the past people or their infected animals, provided by the archaeologists to increase the understanding of the health status and diseases in that time (Chin, 2002). The coprolite specimen represents the intestinal contents that were firstly used by Buckland (1829) in paleontology to describe the mineralized dinosaur feces (Reinhard and Bryant, 1992). Of course not as much as coprolites, the ambers however are also regarded as occasional appropriate natural preservatives for the insects, and the biological agents they carry over time (Poinar Jr and Poinar, 2005). The revealing of mermithid nematode and gordiid hairworm parasites of 100–110 million years ago in amber from Burma and *Paleoleishmania neotropicumis* in the extinct sand fly from 20–30 million-year-old amber are unique examples to define appropriate preservation conditions (Poinar Jr and Buckley, 2006; Steverding, 2017). Through the analysis of digestive tract contents, the Behavioral Nutrition that might have been addressed by the other researchers can be supported or rejected. The definition of Veganism that stated for the Tyrolean Iceman "Ötzi" of 5000 years ago using Stable isotope analysis (SIA) and then has been discussed, was revised later by illustrating the fragments of meat fibers recovered from its coprolites (Dickson et al., 2000). Paleoparasitology may also unfold the habit of consuming raw or undercooked fish in human communities like in the Joseon Dynasty of medieval Korea, following the finding of *Clonorchis sinensis* eggs (Seo et al., 2007). Regarding the details in the lifecycle of certain identified parasites in archeological sites, the specific human behaviors and/or an exotic diet can be predicted within that community. In the same way, observing a lizard's parasitic agent in human coprolites, the feeding on the squamate reptiles can be imagined among those people (Araújo et al., 2013). The existence of some socio-political practices like the human slavery in 1450–1550 AD in France could be also described by tracking the occurrence of *Schistosoma mansoni* in biological remains of that time and region since the parasite has been known endemic to Southeastern Asia (Bouchet et al., 2002). In the same way, traveling to remote geographical regions or neighboring countries will be certified by the identification of parasites known endemic in passengers that have traveled to that given territory. To attain a reliable diagnosis in studying coprolites and their containing materials, however, polynology discipline looks like an advantageous in distinguishing pollen resembling helminth eggs from those real ones (Jiménez et al., 2016). In coprolites, the identifying of *Cistus ladanifer* shrub as the historical aromatic product that might have been used to conceal the unpleasant smelling around the latrines describes a beneficial role of polynology in paleoparasitological investigations (Deforce, 2006). From the other perspectives of the study on

ectoparasites such as human lice, the co-evolution process can be explained based on evidence (Araújo et al., 2000). It is quite clear that the life subsystems and the human operation patterns on the earth have undergone many changes from the time of our earliest ancestors in Paleolithic times to the Neolithic threshold and until recently. In this context, paleoparasitological findings help us to realize how the various biological items involved in the parasite's life cycle have initially emerged, adopted, or possibly eliminated from the environment. Domestication and the beginning of agriculture following the permanent settlement of humans can evidently justify the emergence of new diseases that had not been prevalent before the Neolithic period. For instance, retrieving of ascarid and taeniid eggs in a collected soil sample from a dog's pelvic bones in East Chia Sabz archeological site in Iran dated back to the Neolithic period (8100 BC) provides insights into the transmission of toxocariasis and echinococcosis in Fertile Crescent (Paknezhad et al., 2017). In addition, the human parasitic fauna, however, might have been altered during the Neolithic revolution due to an increase of contact between humans and their nearby animals (Bouchet et al., 2003). Proving the existence of a specific parasite along with its intermediate host in the same region exhibits the natural climatic and environmental conditions of the given region. As an example the finding of Fasciolid eggs in the paleofeces, and recovering of *Lymnaea* (*Galba*) *truncatula* the freshwater snail describes the appropriate natural condition and the existence of biological possibilities for this trematode's intermediate host in that site (Dittmar and Teegen, 2003). To explain the meaningful events over the past, the capability of microscopical detection should be supported by more advanced techniques like aDNA analysis technique. Trying to implement immunological tools such as enzyme-linked immunosorbent assay (ELISA) in paleoparasitology has provided the determination of the past status of protozoan parasitic infections of public health importance, mainly *Entamoeba histolytica* in ancient human populations (Le Bailly et al., 2014). Nowadays scientists are confidently enabled to predict the health status of the past, through identifying the existence of the possible pathogenic agents within the biological remains to some extent (Anastasiou and Mitchell, 2013). In addition, the Next Generation Sequencing (NGS) has also offered another new powerful means of detecting a wide range of biotic elements, by which reconstructing the entire ancient macrobiotic environment of humans and animals is possible (Cano et al., 2014). The current access to this valuable biological banking system has enabled researchers to describe the various biological behaviors such as predator-prey in the wildlife (Chin, 2002), along with the needed potentials in occurrences of zoonotic infections in the far past supported by documents. Traits like carnivory, herbivory, omnivory, and cannibalism can be also described for animals and humans on occasions, through the metagenomic analysis. Revealing bones, fragments, and striated muscles in coprolite of a Cretaceous dinosaur illustrating the fate of a carnivore victim using preferred and selective techniques is also worth mentioning here (Poinar and Boucot, 2006). The achievements in this field of research may also indicate the existence of vector-borne diseases 100 million years ago on the earth through the tracking of the stages of trypanosomes or Early Cretaceous sand (Poinar Jr and Poinar, 2005). This is however interesting that geophagy as a clinical sign (Shinondo and Mwikuma, 2008) that is elaborated in patients suffering from a heavy hookworm infection and trichuriasis can be described by the implementation of the NGS precise technique, illustrating the elements that indicate the presence of soil in the human coprolites. Analyzing ancient intestinal contents has also expanded our knowledge to track the changes that happened during the developmental stages in human life. Taking advantage of these golden specimens, the predominant diets of carnivores, herbivores, and omnivores have been confidently demonstrated through the study on their sterol profiles and bile acids at a Neolithic settlement in the main-land Near East (Ledger et al., 2019). From the perspective of paleopathology, the finding of helminth eggs, known to be involved in human anemia of patients suffering from a heavy worm burden, in the coprolites of mummified skeletons with pathological bone lesions "porotic hyperostosis," demonstrates a unique interdisciplinary medical interpretation (Elleboudy, 2015). Moreover, describing some other phenomena like the differentiation between real parasitic infections and false parasitism "pseudo parasitism" cannot be attained by merely ordinary techniques such as common rehydration. In these cases, the consumption of animal parasitized organs like their infected livers may exhibit the parasite eggs in the consumer's coprolite that should not be regarded as a real infection (Reinhard, 1992). Since the finding of the eggs of few helminths like *Dicrocoelium* eggs in human stool samples cannot be initially attributed to a real process of infection, repeated stool examination is recommended even for the present patients that the point should be also regarded precisely in paleoparasitology to exclude any probable false parasitoses (Le Bailly and Bouchet, 2010). The finding of the oldest *Dicrocoelium* eggs of Near East in a cemetery of Bronze Age (2600–2200 BCE) close to Yasuj city, southwestern Iran indicates the presence of this zoonotic worm at that time that might have infected those people through hunting (Mowlavi et al., 2015a). Paleoparasitological findings can also explain more accurately the real emerging and re-emerging infections that are a topic of discussion in the World health organization (Aufderheide et al., 2004). Meanwhile, the other benefit of interdisciplinary researches like paleoparasitology is practicing techniques that are used in a specific discipline routinely, can be practiced in another field of science. The petrographic thin section which is utilized in geology to study fossilized object's structures was successfully experienced in studying two recovered calcified objects from a grave of an adolescent of 3rd to 4th-century in Amiens (Northern France) (Mowlavi et al., 2014a). Taking advantage of this technique, the capillariid eggs around the hydatid cyst laminated layer were also detected in one slide out of 15 thin-section prepared slides. Meanwhile, a comprehensive study of biological remains attainable within the settlement region in ancient populations can assist the scientists to find a possible medical answer in understanding the reasons related to the vanishing of the past human societies and cultures. This also should be considered that the existence of some biological elements such as nematophagous fungi is another possibility that may overshadow the real status of helminth infections in ancient times. In paleoparasitological investigations in a wide ancient cemetery, the existence of these fungi as natural predators feeding on helminth eggs should be regarded since the real number of positive cases might be overlooked in that archeological site (Leles et al., 2010). *Physaloptera* spp. eggs as the only tracked parasite in one burial site among 320 skeletons studied in Shahr-e Sukhteh archeological site of Bronze Age (2800–2500 BCE) in eastern Iran, can imply the possibility of false-negative results due to nematophagous fungi that have been detected in the same skeleton (Makki et al., 2017). The very important role of appropriate

preservation condition as a key factor in preventing destructive taphonomic processes on biological remains should not be underestimated as it has been demonstrated in sheltered sites (Reinhard et al., 2019). However, based on available evidence in the Hallstatt salt mines archeological site, the salty environments are known as the most appropriate factor in coprolites preservation over time (Bouchet et al., 2003). Meanwhile and referring to the effective role of salt, our previous studies in Chehrabad salt mine archeological site (Sassanid Era, 224–651 CE) in Iran, the intact appearances of the eggs of *Trichosomoides crassicauda*, *Syphacia* sp. and *Trichuris* sp. in rats, *Macracanthorhynchus hirudinaceus* eggs of canine, as well as the eggs of Strongylidae and Anoplocephalidae helminths of herbivore which have been observed in animal coprolites is worth mentioning (Mowlavi et al., 2014b, 2015b; Meigouni et al., 2020). Describing the reasons for the shift from the prevalence of *Trichuris* eggs in the early decades of the 19th century and even earlier times to *Ascaris* eggs half a century later until nowadays has been justified by the biology of helminth eggs and the changes raised in environmental and socio-cultural conditions following urbanization (Trigg et al., 2017). Many other historical realities could be however documented or even rejected based on approved paleoparasitological findings. From the perspective of the human lifestyle, it is expected that in hunter-gatherer societies, uncooked meat should have been the cause of most of the parasitic infections, while the sedentary life could have increased amoebic dysentery owing to crowdedness and more human contacts with the water resources (Reinhard, 2000). In the case of human pinworm infection due to *Enterobius vermicularis* a directly transmitted helminth that is believed to have been originated from Africa and its existence was documented in the North American archeological sites about 10,000 BP, might have been intermittently occurred among ancient hunter-gatherers (Araújo et al., 2015). Jean-Pierre Hugot and colleagues have explained the significant phenomenon by the description of the air-borne enterobiasis in humans when they selected indoor life in caves and left outdoor habits on the route of evolution (Hugot et al., 1999). This interindividual direct transmitted helminthiasis in ancient societies is another subject of interest to be discussed in paleoparasitology (Formaciari and Gaeta, 2014). Parallel to this parasitological fact, tracking of enterobiasis in the 7000-year-old Tehrani woman, following the identification of the *E. vermicularis* egg in her pelvic soil sample has extended the antiquity of human residency in Tehran to 5th millennium BCE while the previous documents in Gheytaieh Cemetery archeological site in the northeast of the city had shown the human settlement background to a closer time in the region (Paknazhad et al., 2016). It is valuable for the interested researchers to understand more about the origin of the parasites. It is also important to note that the identification of the parasites of ancient times that are still current on the Earth is easier than those extinct parasites. However, the identification of those parasites that have been extinct along with their natural hosts together, is a more challenging issue in paleoparasitology (Strona, 2015). Today, looking at the approximately 100,000 museums in the world, it can be expected that a valuable and variant amount of ancient materials obtained from archeological excavations are available to be precisely investigated. These great archeological items however do not certainly include all of the world's apparent and hidden heritage (Statista Research Department, 2020).

In conclusion, the study on these valuable resources and ongoing new biological remains excavating from archeological sites as a unique topic of research can incredibly increase and improve the knowledge of researchers about the emerging parasites, diseases, and the health status among the earliest ancestors of human beings on earth.

Epidemiology

Pinworm infection, also called enterobiasis is caused by the parasitic nematode *Enterobius vermicularis*. The worm is also known as threadworm or seatworm. Enterobiasis occurs worldwide and affects persons of all ages, socioeconomic levels and race, although it is primarily a pediatric condition being most frequent in children. It affects also people living in crowded environments, including caregivers, and within families (household members). In institutions, transmission is facilitated by communal living and possibly by the residents' difficulties in maintaining good personal hygiene which contributes to create a large reservoir of infection (Lohiya et al., 2000).

The relationship between the prevalence of pinworm and gender is controversial. It is generally reported to occur with equal frequency in both males and females. However, some studies indicate that the risk of *E. vermicularis* infection could be higher among male children with a male to female infection frequency of 2 to 1. In contrast to these studies, females sometimes resulted to be affected more often (Wendt et al., 2019) than males (Al-Daoudy, 2005; Al-Daoudy and Al-Bazzaz, 2020).

The highest rate of infection has been observed in younger age group (3–6 years old) with children aged 5–10 years old accounting for over 30% of cases (Kucik et al., 2004) and can probably reflect a lower attention to personal hygiene in small children compared to older ones as well as by the anal scratching being more frequent among small children, facilitating the autoinfection. Educational level among children, overcrowding, socioeconomic condition, and climate could be also related to pinworm infection. Among risk factors, scratching the perianal region, nail biting, putting contaminated toys or utensils in the mouth, as well as close person-to-person contact seem to play an important role. Wang and colleague found that no hand washing before eating, sucking fingers or toys, and scratching of the anus were all factors associated with the infection (Wang et al., 2016).

Pinworm is mainly spread by fecal-oral route and occurs via self-inoculation or through exposure to eggs in a contaminated environment. However, transmission via inhalation is also reported (Rawla and Sharma, 2019). Eggs may be directly transferred from the perianal area to the mouth when hands scratch the perianal region (autoinfection) or may be ingested indirectly, through contaminated objects or surfaces. Occasionally, the hatched larvae can also enter the anus retrogradely migrating to rectum and the small intestine, causing retrograde infection (Schuffner and Swellengrebel, 1949). Reinfection is frequent.

Risk factors

Risk factors for pinworm infection include poor hygiene with particular regard to hand-washing prior to eating, scratching in the perianal region, nail biting (onychophagia), living with an infected individual, being a child and taking care of infected people, especially individuals who are institutionalized. Pets like cats and dogs cannot become infected. Transmission is also possible sexually (Abdolrasouli and Hart, 2009; Waugh, 1974; Baker and Peppercorn, 1982).

Geographic distribution and prevalence

E. vermicularis is the most prevalent gastrointestinal nematode in humans. Pinworm is an exclusive obligate parasite of humans, directly transmitted from person to person with a worldwide distribution, nearly ubiquitous, being very common in temperate and cool climate regions (Ariyathenam et al., 2010; Powell et al., 2013), although the infection is more common in temperate than in tropical districts (Fan et al., 2019).

Climate and soil temperature are limiting factors for some human helminths such as whipworms and hookworms, that are host-specific and without intermediate hosts (Araujo et al., 2008). By contrast, *Enterobius* egg survival is not dependent on climate conditions (Hugot et al., 1999).

In Europe, prevalence rates of 37.0% up to 50% have been reported (Herrström et al., 2001; Burkhart and Burkhart, 2005) although they are generally near 20% (Wendt et al., 2019).

Estimated prevalence among kindergarten and primary school pupils in Europe are generally near 20%. Infants (<2 years of age), adolescents (>14 years of age), and adults are only sporadically infected (Wendt et al., 2019).

In a recent epidemiological study on the occurrence of enterobiasis in Germany, *E. vermicularis* was retrospectively detected in 17.4% of samples between 2007 and 2017. The detection rate increased significantly within the period of investigation and was higher in male than in female patients (20.0% vs. 15.4%). Children 4–10 years old (and their relatives) were most frequently affected. Frequency of detection in children <6 years was evenly distributed throughout the year, whereas in older patients it showed a seasonality with peaks during the winter months (Friesen et al., 2019).

In Italy, a study showed a prevalence in children during the years 2002–03 of 13.4% (Crotti and D'Annibale, 2006).

In Eastern Slovakia, pinworm prevalence was 4.07% in boys and 3.21% in girls. The highest prevalence was recorded in the group of children aged 3–6 years (5.03%). Most of the samples were positive at age 4 and 5 (Dudlová et al., 2018).

Similar results (3% prevalence) were found in children and adolescents from a North-Eastern area of Poland (Zukiewicz et al., 2011).

A Norwegian study found that the parasite is widespread in children. A total of 18% of children tested positive for *Enterobius* eggs, with the highest prevalence (34%) among 6–11 years old (Bøås et al., 2012).

Enterobiasis is the most common helminth infection in the USA, with an estimated rate up to 42 million people (14% of the population) affected by this parasite (Burkhart and Burkhart, 2005), with the highest prevalence in children, institutional populations, and families (Lohiya et al., 2000).

Investigators in other parts of the world report variable estimates of prevalence according to the country. In Korea, the overall egg positive rate (EPR) in children was 10.5% (range 3.3–18.6%), higher in boys than in girls (adjusted odds ratio, AOR: 1.5), and in rural compared to urban area (AOR: 1.2) (Lee et al., 2011).

Prevalence of *Enterobius* infection among preschool children in Henan province, China, showed a significant decrease over a 10-year period. The overall EPR for *E. vermicularis* was indeed, 12.75% in 2003 and 5.13% in 2013, respectively. In both years, the EPR for 5 to 6-year-old children was significantly higher than that of 2 to 4-year-old children. However, positive rates were not significantly dependent on gender or area (Wang et al., 2016).

In Sri Lanka, the highest prevalence rate in children was 37.5% (Suraweera et al., 2015).

A meta-analysis reported high differences in prevalence of *E. vermicularis* among Iranian children, ranging from 1.2% to 66.1%. In particular, boys, and girls showed wide ranges from 2.3% to 65.5% and 1.7% to 65.5%, respectively. When adjusted for the random effect model, the overall prevalence of oxyuriasis among all children, boys, and girls were 17.2% (12.6%–21.8%), 17.2% (12.6%–21.8%), and 16.9% (9.03%–24.8%), respectively (Moosazadeh et al., 2017).

Prehistoric findings

Host-specific human parasites have been used to track ancient migrations (Araujo et al., 2008; Fornaciari and Gaeta, 2014; Reinhard et al., 2016). Evidence of pinworm in ancient populations has been demonstrated in different archaeological sites located in the Americas, Europe, and Asia (Gonçalves et al., 2003). The oldest evidence of a pinworm in Asia has been revealed by the presence of one *E. vermicularis* egg attached to the skeleton sacral region of a female adolescent discovered in the area of Tehran (Iran) and dated to approximately 7000 years ago (Paknazhad et al., 2016).

Enterobius is considered one of the most ancient human parasites (Iñiguez et al., 2003). According to paleoparasitological findings of *Enterobius* eggs from different parts of the world (Fry and Moore, 1969; Hugot et al., 1999; Araujo et al., 2008), the prevalence of pinworm infection seems to be higher in primitive populations of Neolithic period (Paknazhad et al., 2016).

Eggs of *E. vermicularis* were recently identified in coprolites from one pre-Columbian mummy. This is the first evidence of ancient intestinal parasites in Bolivian mummies, being dated from 1150 to 1450 CE (Valverde et al., 2020).

E. vermicularis eggs were also found in human coprolites from archaeological sites in western Utah, USA (Fry and Moore, 1969). These samples, dated at 7837 BCE, are considered the oldest reports of human parasitic infection (Iñiguez et al., 2003).

The discovery of an egg of a parasite of the order Oxyurida in a coprolite from the remains of species of Cynodontia, indicates that the pinworm lineage extends at least as far back as 240 million years (Hugot et al., 2014). This is the oldest record of an oxyurid nematode yet discovered, and is particularly meaningful since the cynodonts are considered a stem-group of the mammals.

Four parasite species were found in the Atacama Desert in coprolites of the Inca period, including pinworm (*E. vermicularis*) (Santoro et al., 2003). *Enterobius vermicularis* eggs were also found in coprolite samples of Salmon Ruins, New Mexico, USA, dating from 1140 to 1280 CE (Reinhard and Camacho, 2019) (Fig. 1).

Biology - Characteristics of the organism

E. vermicularis worms are tiny, thread-like and whitish. At maturity, adult females measure 9–12 mm and have a pointed tail, whereas males are 2–5 mm in length. Gravid adult females migrate to the anal area mostly during the night and deposit thousands of eggs on perianal area. Migration and egg hatching causes pruritus.

Fig. 1 *E. vermicularis* eggs found in coprolite samples of one of the two latrines of Aztec Ruins, New Mexico, USA. With permission of Reinhard KJ and Camacho M (2019) Pinworm infection at Salmon ruins and Aztec ruins: Relation to Pueblo III regional violence. *The Korean Journal of Parasitology* 57(6), 627–633.

Eggs $50\text{--}54 \times 20\text{--}27 \mu\text{m}$ in size, are translucent, with an asymmetric shape and their shell is constituted by two parts. The outer layer facilitates the adhesion of the eggs to the perianal region where they develop in infective larvae in about 4–6 h following oviposition and can survive for 2 or 3 weeks in the domestic environment, mainly on clothing, bedding and other objects or surfaces. Differently from other helminth, eggs of *E. vermicularis* are indeed infective as soon as they are expelled from female worms.

E. vermicularis life cycle takes place in the gastrointestinal lumen. Ingested eggs hatch in the small intestine (duodenum). Larvae mature during their migration to the large intestine. The third larval stadium (L3) represents the infective form of the parasite.

After molting twice, the adult worms copulate and then migrate downwards to the large intestine, where they can be found in large numbers particularly in lumen of caecum, appendix, or ascending colon. The males die soon after copulation; the gravid females, on the other hand, have an overall life span up to 100 days (3 months), reaching the anal canal by means of active migration (Wendt et al., 2019). An adult female can lay more than 10,000 eggs in her lifetime. Oviposition occurs mainly at night, when the host is sleeping. The time interval (incubation period) from ingestion of infective eggs to oviposition by the adult females is of 1–2 months (Fig. 2).

Pinworms generally exhibit high host specificity with humans being the only known host for *E. vermicularis* although occasional infections have been reported in non human primates such as captive chimpanzees (CDC, 2019, <https://www.cdc.gov/parasites/pinworm/biology.html>).

Despite the wide, cosmopolitan, distribution and the high prevalence of enterobiasis in the world, molecular studies for the genotype characterization of *E. vermicularis* are limited. Molecular studies have showed three genotypes (A, B, and C) in *E. vermicularis* from humans and chimpanzees (Nakano et al., 2006; Ferrero et al., 2013). Genotype B is the predominant genotype in human (HayatiHagh et al., 2014). In a work on children in North-Eastern Poland by Kubiak and colleagues, the isolates of the parasite studied were different in terms of the sequences within the cytochrome *c* oxidase subunit 1 (cox1) gene (Kubiak et al., 2017).

Another pinworm geographically distributed in Europe, Africa, and Asia, has been described, namely *E. gregorii*. However, new morphologic and molecular evidence suggests *E. gregorii* likely represents an immature form of *E. vermicularis* (CDC, 2019, <https://www.cdc.gov/parasites/pinworm/biology.html>).

Clinical manifestations

Infection is usually asymptomatic, when the worm is confined in the ileocaecum tract. The most common symptom is perianal itching (pruritus), due to female migration to the anal area.

The larvae and, at a minor extent, adult worms, may penetrate with their cephalic extremity into the mucosa, thus causing ulcerations that may occasionally give origin to hemorrhages and bacterial superinfections. Rarely, diarrhea has been reported in some patients. Other symptoms include insomnia and irritability, particularly in children, loss of appetite, emotional instability, and enuresis in up to 53% of cases (Wendt et al., 2019).

Adult worms reside in the intestine, primarily the ileum and caecum, ascending colon and rectum. Occasionally, infection may involve extraintestinal sites. The parasites can migrate to organs such as appendix, prostate, lungs, and liver. Female genitourinary infections have also been reported in the literature, although rare, with worms migrating to the vaginal area causing vulvovaginitis or urinary tract infection in women (Burkhart and Burkhart, 2005; Rawla and Sharma, 2019). Although of low pathogenicity, serious complications such as infertility or peritonitis may arise (Powell et al., 2013). *E. vermicularis* has also been isolated from the

Fig. 2 Life cycle of *E. vermicularis*. From: https://www.cdc.gov/dpdx/enterobiasis/modules/Enterobius_LifeCycl_Ig.jpg.

male urinary tract (Zahariou et al., 2007). Atypical manifestation of the disease mostly with mental symptoms has also been reported (Karamitros et al., 2017).

Host immune response

The host immune response to helminths is regulated mainly by Th2 cells, which undergo an expansion, and activation which stimulates the production of eosinophils (EO), mast cells, basophils, and specific IgE, by the release of IL-4, IL-5 and IL-13, through the signal transducer and activator of transcription (STAT) 6 activation (Anthony et al., 2007).

In a study by Patsantara et al. (2016), EO, eosinophil cationic protein (ECP), and serum immunoglobulin E (IgE) were found to be higher in pinworm infected than in uninfected children, suggesting a Th2-type oriented immune response activation during this helminth infection. However, EO and ECP were lower in atopic infected children than in those non atopic. These children also exhibited higher total IgE levels compared to non-atopic ones, although they were completely asymptomatic (Patsantara et al., 2016).

Human and animal studies have shown a relationship between allergy and parasitic infections (Reddy and Fried, 2008). A negative correlation between pinworm infection and allergic airway diseases was suggested by Huang and colleagues (Huang et al., 2002). Similarly, enterobiasis has been found to be associated with a decreased risk of allergic wheezing in Turkish school-aged children (Bahceciler et al., 2007).

A change in microbiota composition and in secretory IgA (sIgA) levels after two weeks mebendazole treatment has been observed (Yang et al., 2017). The sIgA provide an important defense against enteric agents. This antibody can bind to adhesion molecules expressed on the surface of by numerous pathogens. Gut sIgA level was low in pinworm infected children, but it was increased in about 50% of the subjects after mebendazole deworming treatment, and it was associated to a higher proportion of probiotic bacteria (Yang et al., 2017).

Diagnosis

The diagnosis of *E. vermicularis* can be confirmed by identifying the female worms or the eggs (Fig. 3).

The diagnostic method of choice is the Scotch-tape test, where a clear adhesive cellulose tape is applied to the anal area early in the morning and then affixed to a slide. Microscopic detection of the characteristic worm eggs confirms pinworm infection. The tape method should be performed in the morning prior to defecation on three consecutive days in order to increase its sensitivity. This varies from around 50% in the case of a single tape test, to about 90% or even more when performed on 3 days (Jeandron et al., 2010).

Stool microscopy examination is not a helpful diagnostic tool since eggs can be detected in only about 5% of fecal samples (Fan et al., 2019). For this reason, pinworm infection is generally thought underestimated. However, stool examination can show adults worms in case of severe infection (Wendt et al., 2019).

A diagnosis of a pinworm infection can also be made by examining the area around an infected person's anus at night with a flashlight to find a female worm. Occasionally, adult worms may be seen on proctoscopy or colonoscopy (Wendt et al., 2019). Serological methods are of no diagnostic relevance and are not commercially available (Fig. 4).

Treatment

The most commonly used drugs are mebendazole (Vermox®), albendazole (Zentel®, Albenza, Eskazole), pyrantelpamoate (Combantrin®), and piperazine. Mebendazole and albendazole are both adulticidal and ovcidal. The first is usually administered at a single dose of 100 mg whereas the albendazole and pyrantel are administered at 10–14 mg/Kg and 10 mg/Kg, respectively. Treatment must be repeated after 2 or 3 weeks because the larval stages are not affected by antihelminth drugs. The following doses are, therefore, essential to achieve the complete destruction of adult worms. Albendazole is not recommended in children under 2 years of age, whereas mebendazole can kill only adults, but not eggs nor larvae (Dudlova et al., 2018).

All the antihelminthic drugs are generally well tolerated causing harmless and short-term side effects, most commonly headache, abdominal pain, and diarrhea. Unlike albendazole, only 7% of mebendazole is absorbed when administered orally as the drug largely remains in the intestinal lumen. This results in fewer systemic side effects and acts effectively when the infection is confined to intestine (St Georgiev, 2001). The safety of drugs used to treat pinworm have not been studied for pregnant women (CDC, 2019).

Since the eggs can be easily spread, all the member of a family or community should be treated with the drug, although they are asymptomatic.

In murine experimental models of infection, a genetic susceptibility to infection has been proved. (Moulia et al., 1993). Indeed, the strain (i.e. genetic) effect seems to be the main parameter which determines the levels of infection (Derothe et al., 1997). Egg counts were significantly higher in some strains compared to other ones. Differences in susceptibility between various species and subspecies of *Mus* have been recently confirmed (Curtis et al., 2017). Differently from previous studies, in this new study, egg counts did not show any difference in regard to age or sex.

Prevention

Hand washing and nail care using soap prior to eating and following defecation is the main preventive measure. Underwear and bedclothes should be changed daily and washed at temperatures of at least 55–60 °C. Household, community members, and sexual partners should also be treated with antiparasitic drugs and the treatment should be repeated after 2 weeks.

Incomplete treatment associated to easy transmission of the parasites may frequently cause reinfection. Indeed, this is common because live eggs are excreted in stool up to a week after the treatment.

Introduction

Named *Oscillaria malariae* by Alfonse Laveran, the Frenchman posted in Algeria who first described this parasite using a basic microscope without staining in October 1880 (Note to the Academy of Medicine, 8 November 1880), the causative agents of fevers, headaches, chills and enlarged spleen were associated with environment, food and drinking water for centuries. Eighteen years later this first description, an Englishman posted in India demonstrated the role of mosquitoes in transmission of this parasite to birds (Ross, 1898). *Plasmodium* is a genus of unicellular parasites that infects mammals, reptiles, birds and most of vertebrates. Few species of *Plasmodium* parasites are responsible for human diseases, but their public health impact is considerable since centuries. While progresses have been obtained from a highly engaged research and political involvement worldwide, Malaria, the disease caused by these parasites in humans, is still one of the main serial killer.

Among the five species that regularly infect human, *P. falciparum* is the most devastating and by far the most studied. Others species have long been considered as less pathogenic, but recent evidence is arising from many studies indicating that *P. vivax* has also a considerable death toll. Studying *P. vivax* has gained more interest among researchers and funders during the last decade, but it is still wrongly considered as a second issue. With the same rational, *P. ovale curtisi*, *P. ovale wallikeri* and *P. malariae* are very poorly considered by the scientific and economic communities. This may be a culpable negligence and the future will tell more about the health impact of these more chronic but still debilitating parasites.

The life cycle is based on a host (mammals, birds, reptiles etc.) where the symptomatic (clinical and/or biological) phase takes place, and a vector (mosquitoes, mostly anopheles) allowing transmission. The host phase of the cycle is the asexual part of the parasite multiplication, while the sexual multiplication occurs within the mosquito's vector. Most of the textbooks are using this sexual/asexual dichotomy to characterize the parasite life cycle and all the steps of the parasite cycle have been perfectly and extensively described in thousands of papers. The *Plasmodium* cycle is more than a complex description of a parasite adaptation to different conditions with the goal of being transmitted. It is a significant timetable for clinic, diagnosis, treatment and public health (Bray and Garnham, 1982).

Plasmodium transmission stages: Gametocytes and sporozoites

The transmission stages of *Plasmodium* are gametocytes (from human to mosquito) and sporozoites (from mosquito to human). Gametocytes are the first step of sexual cycle which occurs inside the anopheline vector. The maturation of gametocytes is done in bone marrow and spleen, depending on species. Mature gametocytes are the only stages circulating in peripheral blood. The

production rate and timing of gametocytes is highly regulated by internal (genetic and epigenetic) and external factors (host, nutrients, lipids, environment). When ingested by mosquitoes, gametocytes are exposed to a major drop in temperature and to xanthurenic acid, triggering their maturation into gametes (Josling and Llinás, 2015). Male gametocytes produce 8 flagellated gametes in the mosquito mid-gut in less than 20 min (exflagellation step) and the female gametocytes evolve into a single macrogametes (Ngotho et al., 2019).

Sporozoites are the infectious stage injected to the dermis during the infected mosquito's bite. Using gliding motility properties, a proportion of these sporozoites can reach the blood-stream in 1–3 h, while others are destroyed by host response (Cowman et al., 2016). The next step is traversal through the sinusoidal barrier, including endothelial cells and Kupffer cells, to liver cells, where sporozoites establish and develop in exo-erythrocytic forms in 2–10 days. All these steps are driven by a complex organization of surface proteins. The central role of circumsporozoite protein in these processes lead to its extensive study as a vaccine target. The evolution of liver stages is different depending to species particularities, with a special interest to *Plasmodium vivax* hypnozoites described below. It was recently stressed that we should clearly define the respective timings between each phase of the parasite cycle (Pinkevych et al., 2015). Time-to-infection, which could be different according to the immune status of the patient, is different from time-to-detection, which highly dependent on the biological methods (microscopy versus PCR). Both timings may be affected by the burden of injected sporozoites and the growth rates of parasites. Thus this information should be taken into account with caution and a clarification is probably needed in the future.

Plasmodium human stages

Up to 40,000 merozoites could be produced in a single liver cell. The budding of merozoite inside vessels lead to the release of these parasites inside the blood flux. Free merozoites invade red blood cells in less than 2 min. The penetration is a very active mechanism requiring deformation of red blood cell, irreversible attachment, and reorientation of the parasite. The merozoite is then propelled inside the red blood cell by the actinomyosin motor, and the membrane fusion entrapped the parasite in the digestive vacuole. Schizogony occurs in 48 h, leading to the egress of 16–32 merozoites in the case of *Plasmodium falciparum*. The intraerythrocytic cycle of *Plasmodium* species is responsible for the occurrence of major symptoms such as fever and anemia due to the regular disruption on infected red blood cells and to the liberation of the parasite pigment (hemozoin). The early trophozoite stage (ring form) is probably poorly involved in the pathology, while late trophozoites and schizontes will sequester in the deep microvasculature, mainly in the brain and the lungs, triggering the endothelial damages responsible for the more severe symptoms. The pathophysiological mechanisms were fully described in details elsewhere (Erice and Kain, 2019; Jensen et al., 2020).

Parasite metabolism

Plasmodium parasites were qualified as voracious consumers of glucose (Olszewski and Llinás, 2011). Parasite increase up to 100-fold the infected red blood cell glucose consumption rate (Qureshi et al., 2020). The energetics needs are primarily provided by glucose fermentation, and this resource is abundant in the serum. The membranes required for the parasite proliferation are produced via a complex mechanism of lipid metabolism, including scavenging of preformed fatty acids from the serum and incorporation into membrane glycerides (Olszewski and Llinás, 2011). The *clag* multigene family encodes the Rhop H1 proteins involved in the formation of channels at the surface of red blood cell. These channels are needed for the acquisition of nutrients (Duraisingh and Skillman, 2018).

The *Plasmodium* genome

The *Plasmodium* genome is haploid except in the mosquito midgut, with fourteen chromosomes, a circular plastid genome and multiple copies of mitochondrial DNA (Su et al., 2019). The genome size of *P. falciparum* is lower (23.2 Mb) than those of *P. vivax* (29.1 Mb), *P. ovale* (33.5 Mb) and *P. malariae* (33.6 Mb). The adenine-thymine contents (AT) are very different among *Plasmodium* species infecting humans, from 80% in *P. falciparum* to 60% in *P. vivax*. The *P. falciparum* genome is highly polymorphic near the subtelomeric regions of the 14 chromosomes where multigene families are encoded. Extensive transcriptomic studies shown that most of the multigene families have clonal variation, leading to the definition of the “variantome” of the parasite (Duraisingh and Skillman, 2018). The epigenetic control of gene expression is under the control of vast array of histone-modifying enzymes including histone deacetylases, histone acetyltransferases and demethylases. *Plasmodium* also shows a large number of single nucleotide polymorphisms and copy number variation. Comprehensive reviews of genomic analysis of *Plasmodium* parasites were published and reader should refer to these papers (Abel and Le Roch, 2019; Escalante and Pacheco, 2019; Galinski, 2019; Ross and Fidock, 2019; Saralamba et al., 2019; Su et al., 2019).

Antigenic and gene expression variation

The parasite has developed a smoke-screen system to escape the host's adaptive immunity. One of this main mechanism is the controlled alternating expression of adhesive surface protein variants (Deitsch and Dzikowski, 2017) The *var* gene family encodes surface antigens named *Plasmodium falciparum* erythrocyte membrane protein 1 (PfEMP1). These surface proteins, as well as the repetitive interspersed families of polypeptides (RIFINs) and subtelomeric variant open reading frame (STEVAR), are highly

involved in the pathogenesis mechanisms of malaria and their role in sequestration of parasites is crucial during cerebral malaria and placental malaria (Wahlgren et al., 2017). These surface antigens are considered as candidates for a vaccine development. Among the sixty *var* genes present in the genome of a single parasite, only one encodes a variant of PfEMP1 at a time. When this surface antigen is detected by the immune response of the host, the parasite switches its expression to another variant. How the parasite turn on or off the expression of these genes has been extensively reviewed by authors (Deitsch and Dzikowski, 2017). RIFINS and STEVOR subvert the host immune system via a still obscure mechanism, probably different from the mutually exclusive manner of *var* genes (Duraisingh and Skillman, 2018). Much less information is available concerning the antigenic variations and immune evasion of the other *Plasmodium* species infecting humans while the immunology of vivax malaria has been extensively studied (Antonelli et al., 2020).

Plasmodium infecting humans

Five *Plasmodium* species are regularly infecting humans: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale curtisi*, *Plasmodium ovale wallikeri*, *Plasmodium malariae*. Among the zoonotic species, *Plasmodium knowlesi* is the most frequently observed in humans.

Plasmodium malariae (Fig. 1)

Plasmodium malariae was named by Grassi and Feletti in 1890. *P. malariae* is the only human parasite (with the zoonotic parasite *P. brasilianum*) presenting an erythrocytic cycle that last for 72 h, releasing 6–14 (average 8) merozoites in the blood stream (Collins and Jeffery, 2007). This regular increase in parasite count was associated with fever peak occurring on the fourth day defining the quartan malaria. The prepatent period after mosquito bites varies between 16 and 59 days, but a recent study demonstrated that the delay to onset of symptoms in travelers could be from 1 day to 1 year (Sutherland, 2016; Teo et al., 2015).

The low parasitemia (around 10,000 parasites/ μ L = 0.25%) observed in patients infected by *P. malariae* is linked to these parameters: slow and low multiplication rates and infection of older erythrocytes (Collins and Jeffery, 2007). This mild infection may last for 60 days without treatment, and it is supposed that the blood stages may persist for years or decades (Vinetz et al., 1998), without identified dormant liver stages. This chronic infection may results in a chronic nephrotic syndrome responsible for poor outcome (Hedelius et al., 2011; Mueller et al., 2007).

P. malariae transmission is present in most of the malaria endemic word, including sub-Saharan Africa, South-East Asia, South America and western Pacific. The seasonal transmission of *P. malariae* seems to be opposite to that of *P. falciparum* in co-endemic areas leading to the hypothesis of specie specific suppression by *P. falciparum* (Bichara et al., 2017; Molineaux et al., 1980).

At least 30 different species of anopheles' mosquitos were involved in *P. malariae* transmission experimentally, and 8 of them were proven to infect humans.

Fig. 1 *Plasmodium malariae* schizontes and trophozoites.

P. malariae is morphologically similar to monkey's parasites *P. knowlesi* (quotidian cycle) and *P. inui* (quartan cycle) from South-East Asia, and to *P. brasilianum* from South America.

A new reference genome for *P. malariae* was recently produced from clinically isolated parasites, allowing extensive *Plasmodium* phylogeny (Rutledge et al., 2017). This study provided evidence that the split between *P. malariae* and *P. malariae*-like parasites (monkeys) occurred 3.5 million years ago, meaning more recently than *P. falciparum*/*P. reichenowi* split (3.0–5.5 million years ago). The genome size of *P. malariae* is 33.6 Mb, with 6540 genes.

Plasmodium ovale* (Fig. 2): *Plasmodium ovale curtisi* and *Plasmodium ovale wallikeri

Plasmodium ovale, first described in 1922 (Stephens, 1922) is transmitted to humans mostly in Sub-Saharan Africa, and infrequently in Western Pacific, Sri Lanka (Wickremasinghe et al., 2008), Vietnam (Gleason et al., 1970), Myanmar (Win et al., 2002), Lao PDR (Toma et al., 1999; Win et al., 2002) and Timor (Baird et al., 1990; Kotepui et al., 2020; Lysenko and Beljaev, 1969). Its prevalence is highly variable according to areas and seasons, but probably underestimates due to low parasitemias, frequent co-infections (Bichara et al., 2017), poor performance of diagnosis methods including light microscopy and rapid diagnosis tests, and mild infection in humans leading to low interest of the scientific and medical community.

Plasmodium ovale prepatent period is 12–20 days, followed by a tertian cycle with a development in erythrocytes that last 49 h for asexual and sexual forms, and to 8–20 merozoites (Collins and Jeffery, 2005). The parasitemias remain at a low level with a peak at 10–12 days.

P. ovale is usually described as a relapsing species due to the existence of hypnozoites in the liver (Collins and Jeffery, 2005). However the evidence for this characteristic is lower than for *P. vivax* (Richter et al., 2010).

A decade ago, Sutherland and colleagues demonstrated that *P. ovale* consists of 2 non recombining species: *P. ovale curtisi* (classic type) and *P. ovale wallikeri* (variant type) (Sutherland et al., 2010) as suspected previously (Win et al., 2004). The new names of these two different species were proposed to honor Christopher Curtis and David Walliker. These two species are sympatric in time and space and were probably separated more than 1 MY apart, leading to a genetic drift preventing fertilization and recombination (Sutherland, 2016). Most of the knowledge on *P. ovale* was obtained prior to this new classification, and evidence for differences in biological, clinical and epidemiological traits between the two *P. ovale* are scarce. One of the difference was the latency period measured at 85.7 days for *P. ovale curtisi* and 40.6 days for *P. ovale wallikeri* (Nolder et al., 2013).

These parasites have gained a renewed interest during the last decade, while most of the cases are uncomplicated mild malaria with favorable outcome. A recent metaanalysis of severity and mortality of *P. ovale* infection included only eight studies (Kotepui et al., 2020). The mortality rate of severe *P. ovale* infections was 0.15%, but this was based on only 2 deaths among 1365 cases. It is thus impossible to compare the mortality rate of *P. ovale* species to those of *P. falciparum* or *P. vivax*, suggesting the fact that we should pay more attention to this species to improve our knowledge which is mainly based on the use of the Donaldson strain for general paralysis therapy during decades.

Fig. 2 *Plasmodium ovale* trophozoites.

Plasmodium vivax (Fig. 3)

Plasmodium vivax was long a neglected malaria parasite compared to *P. falciparum* (Carlton et al., 2011). The recent progresses made during the last decade has highlighted the remaining role in malaria transmission of *P. vivax* in areas where *P. falciparum* incidence were significantly reduced. Vivax malaria was classically designed as “benign tertian fever”, but the availability of more powerful methods for species diagnosis showed that vivax malaria can be responsible for severe disease, including fatal outcomes (Picot, 2006; Picot and Bienvenu, 2009; Price et al., 2007). A recent review on its biology indicated that four key words are linked to future challenges on the way toward malaria elimination: relapse, gametocyte, infectivity, short cycle (Adams et al., 2018).

A list of three cells can be used to stratify the *P. vivax* issues: reticulocytes (no culture), hypnozoites (relapse) and gametocytes (transmission). These issues have knowledge and therapeutic consequences that should be addressed.

The prepatent period of *P. vivax* is 7–8 days, followed by erythrocytic cycle of 48 h, leading to the release of 12–16 merozoites (Galinski et al., 2013). Those merozoites invades young red blood cells for both asexual and sexual development. The preferential invasion of reticulocytes or young red blood cells is a factor limiting parasitemia. The parasite create a network of caveola-vesicle complexes (Aikawa et al., 1977; Barnwell et al., 1990) open to the exterior of the red blood cell. It is suspected to uptake or release toxic metabolites such as lactic acid (de Koning-Ward et al., 2016) and to play a major role in the selection of reticulocytes for parasite growth (Galinski et al., 2013). These complexes can be observed by light microscopy after giemsa staining and are named Schüffner's dots (Schüffner, 1899). *Plasmodium* spp. have the capacity to export proteins beyond the plasma membrane (de Koning-Ward et al., 2016).

Gametocytes circulate early in the infection, leading to the possible vivax malaria transmission by mosquito's bite prior to symptoms and treatment (Bousema and Drakeley, 2011). A gametocyte is fully developed in 48 h and remain only 3 days in circulation. But the production of *P. vivax* gametocytes is continuous, by waves at 5 days intervals and last as long as the infection (Galinski et al., 2013).

The hypnozoites stage of *P. vivax* is one of the most intriguing and challenging stage of malaria parasite (Krotoski, 1989; Krotoski et al., 1982; Markus, 2011). After inoculation of sporozoites by the mosquito, trophozoites penetrate in liver cells. Some of these small (4–5 µm) trophozoites will become dormant for long periods of time, up to two years (Galinski et al., 2013; Petersen et al., 2013). The documented knowledge on the determinants and the biology of these hypnozoites is scarce because they are small, almost inert for the host cell, located inside the liver and difficult to reproduce using in vitro models of hepatocytes culture. Hypnozoites are responsible for relapses of *P. vivax*, which are a major challenge for both complete treatment of individual patient and control of vivax malaria transmission (Olliaro et al., 2016). The risk of early relapse is more associated with tropical climate than temperate zones, and it is supposed that the periodicity is triggered by the seasonality of mosquitoes' bites. If mosquitoes are present during the whole year, the periodicity is short. But if mosquitoes are present only during a season, the occurrence of relapse could be less frequent. It seems that parasites are waiting for the availability of mosquitoes to wake up from hypnozoites in the liver, produce gametocyte, and be transmitted. The number of relapses is higher in tropical areas for *P. vivax* because such adaptation to seasonality didn't drive this evolution required elsewhere (Shanks, 2012).

Fig. 3 *Plasmodium vivax* gametocytes and trophozoites.

Plasmodium vivax is preferentially infecting reticulocytes which represents 0.5–2% of circulating red blood cells. Several proteins have been described as essential for merozoites invasion in reticulocytes, including reticulocyte-binding proteins (RBP) and Duffy binding proteins (DBP). But other mechanisms may be involved since Duffy negative red blood cell phenotypes are permissible for *P. vivax* infection (Cavasini et al., 2007; Popovici et al., 2020). *Plasmodium vivax* infected red blood cells have an increased deformability allowing circulation through small capillary vessels and avoiding splenic entrapment (Suwanarusk et al., 2004).

Plasmodium vivax genome was first sequenced in 2008 (Carlton et al., 2008) from the monkey-adapted lab strain Salvador 1. Then samples from patients were also sequenced providing a fantastic material for further analysis. The evidence of the high genetic diversity of *P. vivax* is a matter of concern in the toward malaria elimination (Neafsey et al., 2012).

The drug sensitivity of *Plasmodium vivax* is decreasing in many parts of the endemic areas, especially in tropical areas where chloroquine is easily circulating and is responsible for a pressure of selection. The Pvmdr1 gene has been described (Brega et al., 2005) and its link with drug resistance and therapeutic failure was documented (Barnadas et al., 2008; Marfurt et al., 2008; Suwanarusk et al., 2008).

***Plasmodium (Laverania) falciparum* (Fig. 4)**

Plasmodium falciparum belongs to a different subgenus because of the shape of its gametocytes and their lengthy development (Bray, 1958; Bray and Garnham, 1982). It is clearly the most impactful *Plasmodium* parasite for humans, and thus the most studied. *P. falciparum* schizogony is complete in 5–6 days after sporozoites injection. Only the youngest forms of erythrocytic stages circulate in the peripheral blood, while the development to late trophozoites and schizonts occurs in the microvasculature of the various organs such as spleen, liver, lung, brain and placenta. *Plasmodium falciparum* is responsible for an increased rigidity of infected red blood cells during the maturation process, resulting in sequestration in small vessels and avoiding splenic clearance.

While the export pathways are easily visible in *Plasmodium ovale* and *vivax* species as Schüffner's dots, it does exist in all the *Plasmodium* species, including Maurer's cleft in *P. falciparum*. These structures are membranous organelles involved in the sorting of parasites proteins outside the parasitophorous vacuole (De Niz et al., 2017).

The maturation of *P. falciparum* gametocytes requires 9–12 days for the development of five morphologically distinguishable stages (Hawking et al., 1971). This maturation time is longer than for other species (mainly 24–60 h) and is associated with a longer survival in the blood circulation (several days compared to 12–24 h). Finally, the morphology of *P. falciparum* gametocytes is also exceptional compared to the almost round forms of gametocytes from other species, giving the name of this specie: *falciparum* comes from “falx” and “parere”. The *P. falciparum* gametocytes stages 2, 3, and 4 are sequestered in the bone marrow. Early and late stages (1 and 5) are circulating in the blood.

Interestingly, the first evidence of regulated cell death of malaria parasite was provided from the analysis of dying parasites during in vitro culture (crisis forms) (Meslin et al., 2007; Picot et al., 1997). Accumulative evidence that the parasite is able to regulate its own growth via a selection of the most viable parasites have been obtained (Al-Olayan et al., 2002; Hurd et al., 2006;

Fig. 4 *Plasmodium falciparum*: ring stage trophozoites.

Meslin et al., 2011a,b; Sow et al., 2015). These observations opened the way to innovative approaches for killing this parasite (Raj et al., 2020).

Plasmodium falciparum is by far the most frequent and deadliest human parasite. It was extensively studied since its first description and a huge number of references is available for reader (Althoff and Abramson, 2020; Gibbons et al., 2018; Jabeena and Rajavelu, 2019; Julien and Wardemann, 2019; Snow et al., 2017).

Plasmodium infecting other animals

Non-human primates

At least 18 *Plasmodium* species (Collins and Aikawa, 1993) were described in non-human primates such as *Macaca* and *Presbytis*, *Hylobates* (gibbons) and *Pongo* (orangutans) (Galinski and Barnwell, 2009). Most of these species show a tertian periodicity except *P. knowlesi* (quotidian) and *P. brasilianum* (quartan). The rhesus monkey (*Macaca mulatta*) is highly susceptible to infection with Asian species, presenting very high parasitemias and a fatality rate over 70%. Aotus and Saimiri monkeys are also very susceptible to *P. knowlesi*, *P. cynomolgi* and *P. fragile*. Among the leucosphyrus group of mosquitoes, *Anopheles dirus* is the most potent vectors of many of non-human primate *Plasmodium*. The link between non-human primate malaria and zoonotic malaria was extensively described (Baird, 2009). More recently, evidence of ape-to-human *Plasmodium* transmission aroused from work conducted in different areas of Central Africa.

Zoonotic malaria

Plasmodium knowlesi

Plasmodium knowlesi may infect humans as shown experimentally in 1932 (Knowles and Gupta, 1932) and observed after natural infection in 1965 (Chin et al., 1965, 1968). The real impact of natural infection in humans has been probably underestimate due to the resemblance of *P. knowlesi* with *P. malariae* under microscope and its proximity with *P. vivax* genome. There is now an increasing knowledge on the role of *P. knowlesi* as a malaria reservoir in Malaysia and in some areas of Southeast Asia and Western Pacific islands (Cox-Singh and Singh, 2008; Divis et al., 2020; Lee et al., 2011). *Plasmodium knowlesi* is the only species responsible for malaria in Brunei and Singapore (Anstey and Grigg, 2019). Surprisingly, *P. knowlesi* was associated with asymptomatic malaria cases in Cambodia, as well as *P. cynomolgi*. But *P. knowlesi* is mainly responsible for mild malaria and severe cases may occur in less than 10% of these cases, leading sometimes to fatal outcome.

Other zoonotic malaria parasites

P. cynomolgi, *P. brasilianum*, *P. inui* and *P. schwezi* were shown to be infectious to humans, inducing severe cases with relatively low parasitemias. Those cases are unfrequently detected, probably because the diagnosis is not suspected or the morphology of parasites is too close: *P. cynomolgi* resemble *P. vivax* and *P. knowlesi* resemble *P. malariae*, for example. A genetic similarity may also be an obstacle to accurate specie diagnosis even using molecular methods. Recently, *Plasmodium simium* was identified in patients living in Rio de Janeiro and infected in the nearby Atlantic forest (Abreu et al., 2019; Brasil et al., 2017).

Avian Plasmodium parasites

The number of bird species is approximately 10,000 in the world, and 55 *Plasmodium* species were reported in 20% of them (Nourani et al., 2020). Four genera of avian hemosporidians have been described: *Plasmodium*, *Haemoproteus*, *Leucocytozoon*, *Fallisia* (Fecchio et al., 2020). *Plasmodium* genus shown 5 sub-genera. *Plasmodium gallinaceum* and *P. relictum* are among the well-known species of avian malaria. The life cycle of birds *Plasmodium* is almost the same than in mammals, while pre-erythrocytic cycle may occur in bone marrow or reticuloendothelial system and erythrocytic cycle in immature or mature red blood cells. The morphological characteristics of avian *Plasmodium* have been extensively reviewed by authors (Fecchio et al., 2020). Culicidae mosquitos (including *Aedes*, *Anopheles* and *Culex*) are frequent vectors to birds. Migrating birds are exposed to different pathogenic species and may spread these parasites to resident hosts, and favor apparition of new zoonotic agents.

Murine Plasmodium

Four *Plasmodium* species naturally infect African rodents: *Plasmodium berghei*, *P. vinckei*, *P. yoelii*, and *P. chabaudi*. These parasites were widely used in experimental infections and were considered as models for biological and therapeutic studies (Yoeli, 1976). However, the relevance of these models for human malaria were subject of debates (White et al., 2010). The distribution of these parasites is limited to the Congo Basin (Boundenga et al., 2019; Carter and Walliker, 1976). Two species, *Plasmodium yoelii yoelii* and *Plasmodium berghei*, developed mainly in reticulocytes, while the other two, *P. chabaudi* and *P. vinckei* invaded mature erythrocytes.

Plasmodium berghei (Vincke and Lips, 1948) (named in honor of Professor L. van den Berghe) was described as a natural infection in the blood of Congo tree rat (*Thamnomys surdaster*). This parasite was then transmitted to laboratory rats and mice. The erythrocytic cycle requires 22–24 h with a preferential invasion of reticulocytes and the schizonts released 6–20 merozoites. The experimental

infection of Congo tree rats led to 20% mortality in 15–19 days, while 80% of animal maintained a fluctuating parasitemia. The mortality after experimental infection in mice is higher and faster, depending on the number of parasites in the inoculum. In 1968, Bafort isolated the ANKA strain *P. b. berghei* (ANKA came from ANtwerpen and KAtanga) which shows an erythrocytic cycle of 43 h, earlier than do other strains (Landau et al., 1970). This strain was widely used as a model of cerebral malaria (Bienvenu and Picot, 2013).

Plasmodium vinckei was first isolated by Vincke, by the River Kinga (Katanga, Democratic Republic of the Congo). *Plasmodium chabaudi* was first described by Landau near Bangui (Central African Republic) in 1965 as well as *P. b. yoelii* isolated in 1965 near the field station of La Maboke in the Central African Republic (Landau and Cbabaud, 1965). *Plasmodium berghei yoelii* was later elevated to a status of a species by Killick-Kendrick in 1975: *Plasmodium yoelii*.

Conclusion

The aim of this review was to up-to-date the basic knowledge on *Plasmodium* parasites biology. It was not to detail malaria as a disease, including epidemiology, symptoms, immunology, treatment and vaccination, neither entomological aspects, which may require a full text-book. Important knowledge gaps are still to be filled with the objective of malaria elimination and eradication. The exact mechanisms used by the parasite to adapt itself to different hosts, to different biological environment, to therapeutic and immunological pressures are not fully depicted. It is clear from the fight against *Plasmodium falciparum* malaria that the “test-treat-track” strategy will not be sufficient to achieve complete elimination, while the disease is under control in many endemic areas (Bienvenu et al., 2019). Basic researches on the metabolism of *Plasmodium*, the regulation of parasite growth, the parasite cell death (Meslin et al., 2007; Picot et al., 1997), the active interplay between parasites and the host in a dynamic perspective, the transmission bottleneck (Meibalan and Marti, 2017) may open new opportunities to fight against the incredible plasticity of this well adapted parasite.

As regards malaria the reader is referred to the review published by White et al. (2014) and for severe malaria to Mer et al. (2019).

Background

Schistosomiasis is a neglected tropical disease caused by blood flukes (trematode parasites) belonging to the genus *Schistosoma*. It is a vector-borne disease transmitted by several species of freshwater snails, and is associated with two main clinical forms: intestinal schistosomiasis and urinary (or urogenital) schistosomiasis.

The species responsible for intestinal schistosomiasis in humans are six: *S. mansoni*, transmitted by *Biomphalaria* spp. snails; *S. japonicum*, transmitted by *Oncomelania* spp. snails; *S. mekongi*, transmitted by *Neotricula* spp. snails; *S. malayensis* transmitted by *Robertsiella* spp.; *S. guineensis* and the related *S. intercalatum*, transmitted by *Bulinus* spp. (McManus et al., 2018).

The only species responsible for urinary (or urogenital) schistosomiasis in humans is *S. haematobium*, transmitted by *Bulinus* spp. snails.

S. mansoni, *S. mekongi*, *S. japonicum* and *S. malayensis* affect other mammals in addition to humans. *S. mansoni* is found in rodents and primates, and *S. mekongi* in dogs and domestic pigs, although the role of animal reservoir in sustaining transmission is limited. *S. japonicum* infects a wide range of animals including bovines, dogs, pigs, horses, goats and rodents (more than 40 animal species have been shown to be susceptible); it is considered a true zoonosis as animal reservoir significantly sustain transmission in endemic areas, as in the case of water buffaloes in China. *S. malayensis* mainly infects rodents but can occasionally infect humans (Gordon et al., 2019).

More than 10 other schistosome species are animal parasites; they may occasionally infect humans, but parasitic larvae rarely reach adult stage in the human host.

The causal agent of schistosomiasis was first identified and described by the German physician Theodor Bilharz in 1851, while performing an autopsy at Qasr el-Ayni hospital in Cairo (McManus et al., 2018). The new parasite was initially called *Distomum haematobium* by Bilharz himself, but was renamed *Bilharzia haematobium* in his honor in 1856. Eventually the International Commission on Zoological Nomenclature decided to name the genus *Schistosoma*, in 1858. In reason of the above, schistosomiasis is also known as bilharziasis or, although incorrectly, bilharzia.

Occurrence and epidemiology

Schistosomiasis is a global disease, whose transmission is still reported from a large number of countries. Among the species affecting humans, only *S. haematobium* and *S. mansoni* have a wide geographical distribution (WHO, 2012).

- *S. haematobium* is found in sub-Saharan Africa, northern Africa, the Middle East and Europe (Corsica, France) (Kincaid-Smith et al., 2017; Rothe et al., 2021).
- *S. mansoni* is found in large portions of Africa (mainly sub-Saharan Africa and Nile valley), in the Arabian peninsula (Saudi Arabia, Oman, Yemen), in some South American countries (Brazil, Venezuela, Suriname), and in the Caribbean.
- *S. guineensis* is found in West and Central Africa.
- *S. intercalatum* is found only in the Democratic Republic of the Congo.
- *S. japonicum* is found in China, the Philippines, and in the island of Sulawesi (Indonesia). Despite its name, it is no longer transmitted in Japan, where disease control efforts led to its elimination in the 1970s.
- *S. malayensis* is found only in Malaysia (Chuah et al., 2019).
- *S. mekongi* occurs in limited areas of Cambodia and Laos, along the Mekong river.

Overall, transmission of human schistosomiasis is still reported from or presumed to occur in 78 countries (WHO, 2012, 2021). Of them, 27 countries have low levels of transmission, while the other 51 have moderate or high transmission levels still requiring preventive chemotherapy through mass treatment interventions.

Recently *S. mansoni*, *S. haematobium*, *S. mekongi* and *S. japonicum* cases have been reported from Myanmar (Gordon et al., 2019), and *S. haematobium* (Sah et al., 2020) and *S. japonicum* (Bajracharya et al., 2020) from Nepal. However, these findings require further investigation before being confirmed.

Focal distribution of schistosomiasis even within small geographical areas is well-known. Focal distribution implies that prevalence and intensity of infection may vary significantly, even between two contiguous villages. This is because the cycle of schistosomiasis is highly dependent on the environmental variables such as existence of freshwater bodies, presence of suitable intermediate host snails and human behavioral patterns of contact with water. Such patterns may be related to domestic (e.g. cloth-washing), recreational (e.g. playing and swimming in ponds, lakes and rivers) or professional activities (e.g. fishing). Lack of access to clean water as well as poor sanitation and limited hygiene practices also play a role in shaping epidemiology of schistosomiasis (WHO, 2012; Gordon et al., 2019; Kulinkina et al., 2019).

As a reflection of the above factors, people infected with schistosomiasis may belong to diverse age, gender and professional groups; nevertheless, children of school age, adolescents and adults are usually those harboring the highest levels of prevalence and intensity of infection.

Various indicators are alternatively used to quantify the relevance of schistosomiasis as a public-health problem. Population at risk of infection (i.e. living in endemic areas) is estimated at 750–800 million, while people infected are estimated at more than 200 million (Steinmann et al., 2006). Mortality is estimated at about 24,000 deaths per year (WHO, 2021). The Global Burden of Disease Study 2016 estimated the global burden of schistosomiasis at 2.5 million disability-adjusted life years (DALYs) (WHO, 2018, 2021). Nevertheless, consensus is generally lacking on calculations applied to schistosomiasis because of the limited reliability of available epidemiological information.

To overcome the problem, WHO rather applies an operational definition, i.e. number of people requiring preventive chemotherapy with praziquantel (PZQ). Estimates indicate that in 2019 approximately 236.6 million people required preventive chemotherapy globally, of which 128.3 million school-age children and 108.3 million adults (WHO, 2020). Of them, the vast majority (211.5 million; 89.4%) were living in the WHO African region; 20.6 million (8.7%) in the Eastern Mediterranean region; 2.9 million (1.24%) in the Western Pacific region, 1.6 million (0.7%) in the region of the Americas; only 22,000 in the South-East Asia region; and none in the European region.

Causative agents

The parasites

Schistosomes life cycle implies transformation of the parasite in successive forms: egg, miracidium, cercaria, schistosomulum and adult worm (Sobhon and Upatham, 1990).

Eggs differ in shape and size. They measure $50\text{--}240 \times 35\text{--}85 \mu\text{m}$ and are characterized by a spine whose position and shape varies according to the species and can guide its identification (terminal spine in *S. haematobium*, *S. guineensis* and *S. intercalatum*; lateral in other species). The number of eggs released daily by a female worm varies between 1500 and 3000 according to the species. Each egg contains a miracidium. The egg hatches in the environment and releases the miracidium when optimum temperature and illumination are present.

The miracidium is a ciliated larval stage. Miracidia differ in size and shape according to the schistosome species but not in behavior and morphology. The general morphological feature of the miracidia comprise a hemispheric structure named *terebratorium*, and epidermal plates covered by cilia. The miracidia have a primitive gut, a pair of cephalic penetration glands, a nervous system and an excretory system. Miracidia swim with the cilia to find and penetrate a suitable snail in 8–12 h or die.

Penetration is initiated by the mechanical action of the miracidium's apical papilla which breaks the snail epithelium. It is facilitated by histolytic secretions from the glandular cell. When penetration is complete, the ciliated membrane of the miracidium disappears. Few days after, the miracidium develops into a sporocyst, which subsequently gives rise to thousands of cercariae by asexual reproduction. The period of development from the miracidial penetration to the production of mature cercariae varies according to the species (6–9 weeks).

Cercariae are the freely swimming, short-lived stage of *Schistosoma* spp. They measure approximately 500 µm in length and their emergence from infected snails is characterized by a periodicity which is linked to the water contact habit of the natural host. The peak of cercarial shedding of *S. haematobium* occurs at noon between 10:00 am and 4:00 pm while for *S. japonicum*, it happens at night. The number of cercariae daily produced varies: it is about 200 for *S. haematobium* and 250–600 for *S. mansoni*. In oriental species, it is usually lower, e.g. 15–160 for *S. japonicum*. Cercariae may survive in fresh water up to 72 h (Nelwan, 2019). Cercariae have a forked tail that facilitates their movements. After penetration of the skin of the definitive host, they transform into schistosomula.

After developing to mature worms and pairing, schistosomes migrate to relevant venous districts where eggs laying begins. The period from penetration of the cercaria to the shedding of eggs may range from 6 to 10 weeks. Adult schistosomes measure 6.5–20 mm. The adult male is thicker and shorter than the slender and longer female, and the male has the gynaecophoral canal in which the female is held during copulation.

The snails

Two snail families are involved as intermediate snail host for human schistosomiasis (*Pomatiopsidae* and *Planorbidae*). *Littorinidae*, *Thiaridae*, *Pachychilidae*, *Cerithidae*, *Potamididae* and *Planaxidae* families are involved in the transmission of other schistosomes.

Each of the schistosome species has its characteristic spectrum of intermediate snail hosts. The intermediate hosts of *S. mansoni*, *S. haematobium* and *S. intercalatum* belong to the family *Planorbidae* (Brown, 1994), while those of *S. japonicum*, *S. mekongi* and *S. malayensis* belong to the family *Pomatiopsidae* (Sobhon and Upatham, 1990).

Among the *Planorbidae*, various species of *Biomphalaria* serve as intermediate hosts for *S. mansoni* and certain *Bulinus* species are intermediate hosts for *S. haematobium* and *S. intercalatum* (Brown, 1994). Among the *Pomatiopsidae*, certain subspecies of *Oncomelania hupensis* are known to transmit *S. japonicum*; *Neotricula* spp. transmit *S. mekongi* and *Robertsiella* spp. transmit *S. malayensis* (Sobhon and Upatham, 1990).

Biomphalaria spp. and *Bulinus* spp. are aquatic and hermaphroditic snails which can be found in almost all types of water bodies, ranging from small temporary ponds or streams to large lakes and rivers (Brown, 1994). Artificial water bodies such as irrigation canals and dams are particularly suitable habitats and, because of the intense human–water contact, may play a very important role in transmission of schistosomiasis. Both species are usually found in shallow waters and often in association with aquatic plants; in some of the large lakes they may be found also at considerable depth, e.g. *Biomphalaria* spp. in the East African lakes and *Bulinus nyassanus* in Lake Malawi.

Oncomelania spp. snails are small, amphibious and dioecious. Females tend to be larger than males. Eggs are laid singly on solid objects. Hatching occurs after 10–25 days, depending on temperature, and newly-hatched snails pass through an aquatic stage of 1–2 weeks. Snails reach sexual maturity after 10–16 weeks and may live for 24–35 weeks (Leonardo et al., 2020). *Oncomelania* spp. inhabit flood plains, especially artificial habitats resulting from agricultural development, such as drainage and irrigation channels, roadside ditches, and rice paddies. Snails are found primarily on the banks of flood plains, but more rarely in very shallow waters (i.e. depth less than approximately 20 cm). Habitats preferred by *O. hupensis* are shaded by vegetation, and the temperature is relatively constant and cool. Water currents of above 0.14 m/s are generally unfavorable for *O. hupensis* (Leonardo et al., 2020).

Neotricula aperta snails transmit *S. mekongi*, which primarily infects humans across the central Lao People's Democratic Republic and eastern Cambodia. Three strains of *N. aperta* have been identified on the basis of body size and mantle pigmentation. All three strains are suitable hosts for *S. mekongi* but in nature only the γ -strain is known to be epidemiologically significant. *N. aperta* is found in large rivers in central Laos, Thailand and eastern Cambodia.

The intermediate hosts of *S. malayensis* are species of *Robertsiella* (*Pomatiopsidae*: *Triculinae*), that are very small snails. *R. kaporensis* may be found in small streams attached to rocks, leaves and twigs. *R. silvicola* lives in seepages and springs (Sobhon and Upatham, 1990; Chuah et al., 2019).

Several schistosomes of birds and mammals (e.g. *Trichobilharzia ocellata* (La Valette), *Gigantobilharzia* spp., *Ornithobilharzia* spp., as well as *S. bovis*, *S. margrebowiei* and *S. rhodhaini*) may penetrate human skin; cercariae can cause an allergic reaction (cercarial dermatitis or *swimmers' itch*), but do not progress into further development stages. Exposure of man to such schistosomes mainly occurs in water bodies of temperate climate zones, but may also occur in some areas endemic for human schistosomiasis, thus confusing serodiagnostic techniques.

Several factors determine the distribution and the abundance of the snails. Snail presence is dependent on physical and chemical factors such as hydrogen ion, dissolved oxygen in water, light, the geology (type of soil), temperatures, rain fall and water level, water chemistry (pH, concentration of mineral), presence of food for the snails (algae) (Sobhon and Upatham, 1990; Leonardo et al., 2020).

Mode of transmission and life cycle

Schistosomiasis is transmitted to humans when cercariae shed by infected snail intermediate hosts in freshwater bodies penetrate through the skin; this is the result of direct contact with infested water. Cercariae are attracted to the human host by chemical and physical factors (e.g. temperature). Once inside the host, cercariae lose their tail and develop into immature schistosomula, which enter the venous circulation and reach subsequently the right heart, the lungs, the left heart, the arterial circulation and the venous

portal system, where they mature into separate-sex adults (length ranges from 6 to 28 mm, depending on sex and species). Here adult worms form a male-female pair and migrate to the bladder venous plexus in the case of *S. haematobium* and to the mesenteric veins of the bowel and rectum in the case of all other species. Approximately 5 weeks after infection, female worms start producing eggs in the bloodstream. Eggs eventually reach the bladder lumen (in the case of *S. haematobium*) and the intestinal lumen (all other species) and are excreted in urine and faeces, respectively. When in contact with freshwater, as in the case of defecation or urination in proximity of a pond or stream, eggs hatch and release miracidia (free-swimming ciliated larvae). Miracidia then penetrate a suitable intermediate snail host, develop into sporocysts and further multiply by two asexual reproduction cycles, eventually giving rise to numerous cercariae. Cercariae subsequently emerge from the snail in response to sunlight and contaminate freshwater bodies, thus creating the conditions for contact with the human host and closing the *Schistosoma* spp. life cycle (Fig. 1).

Host–parasite interrelationships

S. japonicum and *S. mekongi* are highly zoonotic species, involving intense transmission between human and animals (Sobhon and Upatham, 1990; McManus et al., 2018; Budiono et al., 2019; Gordon et al., 2019; Leonardo et al., 2020). Rodents and non-human primates are also involved in the transmission of *S. mansoni* (Catalano et al., 2020; Kebede et al., 2020). *S. malayensis* is mainly an animal infection affecting rodents (*Rattus muelleri* and *R. tiomanicus*), but its eggs have been documented in humans, indicating that

Fig. 1 Life cycles of *Schistosoma mansoni*, *Schistosoma haematobium*, and *Schistosoma japonicum*. (A) Paired adult worms (larger male enfolded slender female). (B) Eggs (left to right, *S. haematobium*, *S. mansoni*, *S. japonicum*). (C) Ciliated miracidium. (D) Intermediate host snails (left to right, *Oncomelania*, *Biomphalaria*, *Bulinus*). (E) Cercariae. (Colley et al., 2014).

the worm can reach sexual maturity in the human host (Chuah et al., 2019). Hybridization between human species such as *S. haematobium* and *S. guineensis* (Moné et al., 2012), and also between human and animal species has been suspected (Brémond et al., 1993), and documented recently in Africa (Webster et al., 2013; Moné et al., 2015; Léger and Webster, 2017; Catalano et al., 2018; Sene-Wade et al., 2018). *S. haematobium* can also hybridize successfully with livestock schistosome species and maintain its capacity to infect humans. Likewise, other hybridized livestock *Schistosoma* species can also infect humans (Moné et al., 2015; Léger et al., 2016; Sene-Wade et al., 2018).

Pathology, clinical manifestations, and phases of development of the diseases

In the human host, adult worms of *Schistosoma* spp. reside in mesenteric and pelvic venules where they copulate. The usual location may vary from species to species: mesenteric and hepatic veins for *S. japonicum*, *S. mansoni*, *S. malayensis*, *S. intercalatum* and *S. guineensis*, the perivesical venous plexus for *S. haematobium*.

Eggs are released by the female worms in the bloodstream and get trapped in contiguous organs, especially the intestine, bladder and genitourinary tract; they may also be carried away by the bloodstream and embolize different organs, typically the liver in the case of intestinal schistosomiasis. Once lodged in the organ's tissue, eggs evoke a granulomatous reaction resulting in inflammation and eventually tissue fibrosis. The chronic inflammation of the organ tissues leads to the progressive translocation of the eggs through the organ walls toward the lumen (intestinal or bladder) where they are finally released, thus being expelled from the human host with urine or faeces and contaminating the environment (Gryseels, 2012).

Granulomatous reactions around eggs trapped in organ tissues are the key events leading to schistosomiasis-induced morbidity. Granulomas are formed by inflammatory cells (e.g. eosinophils, neutrophils, lymphocytes and macrophages) that accumulate around eggs as a response to their presence; active granulomas are progressively replaced by fibrous tissue (Schwartz and Fallon, 2018). The development of morbidity entails therefore the presence of mature adult worms and well-established egg production. The severity of morbidity is proportionate to intensity of infection, i.e. the number of worms infecting a person, that can be measured by proxy in terms of excretion of eggs in stools and urines.

In intestinal schistosomiasis, especially in the case of *S. mansoni*, *S. japonicum* and *S. mekongi*, lesions such as ulcerations, pseudopolyps and microabscesses can be detected in the bowel. From a clinical perspective, this may translate into abdominal pain, blood in stools and altered bowel habits.

Embolization of eggs to the liver determines typical granulomatous reactions and fibrosis along the branches of the portal venous system (periportal fibrosis), eventually leading to portal branch occlusion and consequently portal hypertension and ascites, possibly associated with spleen hardening and enlargement; liver functions however usually remain normal. Severe, advanced cases are characterized by superficial abdominal blood vessel dilatation, spleen enlargement, and esophageal varices that are bleeding-prone and may rupture, with risk of hematemesis and death. No association between the agents of intestinal schistosomiasis and cancer has been demonstrated.

In urinary schistosomiasis caused by *S. haematobium*, polyps and masses protruding in the lumen, and fibrosis of the wall, are common finding. The opening of the ureter in the bladder may be affected by chronic inflammation, thus leading to reflux of urine and eventually to hydronephrosis and hydronephrosis. The main sign associated with urinary schistosomiasis is hematuria, although vaginal bleeding and dyspareunia (pain during sexual intercourse) may be present when the female genital tract is affected, and be caused by lesions in the vulva (e.g. nodules) and the Fallopian tubes; other complications may include early abortion, ectopic pregnancy and infertility. Damage to prostate and seminal vesicles may lead to painful ejaculation and infertility in males. In both sexes, urogenital schistosomiasis is a risk factor for Human Immunodeficiency Virus (HIV) infection, mainly because of physical damage to genital mucosae. A causal relationship has been established between *S. haematobium* infection and the squamous cell carcinoma of the urinary bladder, and in 2009 *S. haematobium* was included in Group 1 (extensively proven carcinogens) by the WHO International Agency for Research on Cancer (IARC) (McManus et al., 2018).

More rarely, eggs may reach other organs, causing ectopic schistosomiasis (Schwartz and Fallon, 2018).

Eggs reaching the cerebral or spinal venous plexus cause inflammatory reactions in the central nervous system. This may give rise to neurological complications, whose clinical manifestations may vary depending on the site and include transverse myelitis, epileptic seizures, encephalopathy with headache, visual impairment, motor deficits and ataxia (reduced coordination of voluntary muscle movements). The overall clinical picture is usually referred to as neuroschistosomiasis (Carod-Artal, 2010).

In pulmonary schistosomiasis eggs reach the lung capillaries and cause granulomas in the perialveolar area. The resulting fibrosis may lead to pulmonary hypertension and *cor pulmonale* (an enlargement of the right ventricle of the heart due to increased pressure in the lung capillaries) (Gryseels, 2012; Knafl et al., 2020).

In addition to chronic pathology as described above, schistosomiasis is also associated with acute pathology. The associated clinical picture is also referred to as "acute schistosomiasis".

A transient cutaneous rash may persist from hours to days at the site of cercarial penetration, especially in the case of people not previously infected, as in the case of tourists to endemic areas. Such cercarial dermatitis is comparable to the *swimmers' itch* occurring in human exposed to animal (usually avian) cercariae.

Another form of acute pathology is the Katayama fever (also called Katayama syndrome or disease), which is a systemic hypersensitivity reaction to schistosome (migrating larvae) and circulating immune complexes, usually occurring weeks to months after a primary infection (infection in non-immune people). Symptoms may include fever (usually nocturnal), cough,

headache, fatigue and myalgia; eosinophilia and transient pulmonary infiltrates (visible on chest radiography) are also common findings. As in the case of the cutaneous rash, Katayama fever is common in tourists and travelers and is infrequently reported in residents of endemic areas (Ross et al., 2007). This is because the conditions determining its pathogenesis almost exclusively occur in individuals exposed to *Schistosoma* spp. infection for the first time, probably in reason of the lack of early-life sensitization, either in utero or during the first years of life, which on the contrary are common in populations living in endemic areas (Gobbi et al., 2020).

In the case of infections by *S. japonicum*, however, Katayama fever may occur in people living in endemic areas and with a history of previous infections, as in the case of the endemic area located in Katayama district, Hiroshima prefecture (Japan), where it was first described in the 19th century (Ishii et al., 2003). In *S. japonicum* infections, Katayama fever may be associated with severe manifestations including persistent fever, diarrhoea, abdominal pain, hepatomegaly, and generalized rash (Gryseels, 2012; McManus et al., 2018).

In acute schistosomiasis, eggs are usually not found in urine or stool samples, and serological tests or PCR may help in establishing a diagnosis. As worms are still juvenile, treatment with praziquantel will have no effect; symptomatic treatment including use of corticosteroids should be considered. Artemisinin appears to be effective against schistosomula (Utzinger et al., 2000). 4–5 weeks later the patient should be examined for schistosome eggs and, if found positive, treated with praziquantel.

Immune response, immunopathology, and immunity

The interaction between the host's immune system and schistosomes is complex. It involves the different stages of the life cycle of the parasite, which may be present in the body of the host (cercaria, schistosomula, adult worms and the parasite eggs). Immune responses against cercariae and possibly other parasite stages are important for development of resistance to reinfection, whereas responses toward egg antigens are responsible for the pathology in schistosomiasis (McManus et al., 2018).

Protective immune responses against schistosomes develop slowly over a period of 10–15 years, and children of <10 years of age in schistosomiasis-endemic areas are susceptible to reinfection after treatment of the schistosome infection, whereas adults are usually resistant. This observation may also explain the characteristic age-prevalence and age-intensity curves observed in schistosomiasis endemic areas (McManus et al., 2018).

Following infection, cercariae develop into schistosomula which migrate through the host body, eliciting a type 1 (cell-mediated) immune response characterized by increased release of interleukin (IL)-12 and interferon (IFN)- γ . This response persists for a few weeks, and is mainly targeted at worm antigens. However, as soon as schistosomula mature into adult worms and start to produce eggs (5–6 weeks after infection), the immune response shifts toward type 2 (antibody-mediated). Type 2 immune response is characterized by decreased production of IFN- γ , expansion of CD4+ T helper (Th) 2 cells, eosinophils, and basophils, increased production of IL-4, IL-5, and IL-13, and an isotype switch toward IgG1 and IgE (Schwartz and Fallon, 2018). Unregulated production of IL-13 is specifically responsible for liver fibrosis (Colley and Secor, 2014). During the chronic phase of infection (> 3 months), the magnitude of the Th2 response decreases, which coincides with a reduction in granulomatous inflammation around eggs, while regulatory T and B cells emerge leading to a state of immune hyporesponsiveness (Schwartz and Fallon, 2018).

Chemotherapy with PZQ affects the development of individual protective immunity. PZQ kills adult schistosome worms, thereby providing passive immunization through an antigenic stimulus delivered as adult worms die (Oettle and Wilson, 2017). Treatment with PZQ has also been shown to alter the relationship between human host's age and antibody response (which reflects age-related exposure to parasite antigens and the age-related acquisition of resistance to infection) (Mutapi et al., 2003).

Antigens released by schistosomes damaged by PZQ treatment accelerate the acquisition of an immune response which confers resistance to reinfection (Mutapi et al., 1998). This protective immunity may also lead to reduced egg production in infected individuals, a phenomenon observed in *S. haematobium* (Wilson et al., 2014), but not seen for *S. mansoni* infections (Agnew et al., 1996).

Control: Diagnoses, prevention, and treatment

Diagnosis

Detection of parasite eggs in the stool and urine is the gold standard for diagnosis of schistosomiasis.

For diagnosis of infection with *Schistosoma* spp. responsible for intestinal schistosomiasis, stool samples can be examined for the presence of parasite eggs. The Kato-Katz thick smear is the most frequently employed technique, especially in population-based surveys implemented for mapping or monitoring and evaluation purposes. Although the Kato-Katz has low sensitivity if only one stool sample from each subject is examined, its sensitivity can be increased by multiple stool sample examinations from the same individual (Utzinger et al., 2015; McManus et al., 2018). However, multiple examinations are not often carried out as this makes the technique impractical for wide-scale field diagnosis.

Concentration techniques for stool samples have been developed and evaluated. Examples of these tests are the Merthiolate-Iodine-Formaldehyde concentration technique (MIFCT), the Merthiolate-Formaldehyde concentration technique (MFCT), and the Formaldehyde-Ether concentration technique (FECT, formol-ether). Sedimentation techniques such as McMaster, or flotation techniques such as FLOTAC and Mini-FLOTAC (Barda et al., 2014; Allam et al., 2020) can also be employed. These tests, however, are time consuming, laborious to perform, and also impractical for field-based screening.

For urogenital schistosomiasis, examination of urine samples using a filtration technique and microscopy to detect *S. haematobium* eggs was the basis of early studies on this species of schistosome and is still widely used for population-based surveys implemented in endemic countries for mapping or monitoring and evaluation. Various urine concentration techniques have been developed to increase sensitivity of the test.

For people from non-endemic areas or living in low transmission areas, serological and immunological tests may be useful to show exposure to infection and highlight the need for thorough examination and treatment. In an elimination scenario, these tests may also have a role in showing decline of transmission and eventually demonstrating its interruption (Utzinger et al., 2015; Hinz et al., 2017; McManus et al., 2018).

Methods to detect schistosome antigens in the body fluids of infected individuals have been developed. An example of these methods is the use of monoclonal antibodies to detect schistosome antigens that are circulating in the blood and excreted in the urine. The most promising and extensively studied are tests that can detect two proteoglycans regurgitated by adult worms in the bloodstream, the Circulating Anodic Antigen (CAA) and the Circulating Cathodic Antigen (CCA) (Utzinger et al., 2015; Danso-Appiah et al., 2016; Bärenbold et al., 2018). Detection of CAAs or CCAs is an indication of active infection. Commercially available CAA/CCA kits based on enzyme-linked immunosorbent assay (ELISA) or monoclonal antibody techniques have shown excellent sensitivity and specificity, and have been used to detect both *S. mansoni* and *S. haematobium* infections in urine and serum samples. A point-of-care (POC) urine assay test for detection of *S. mansoni* CCA in urine sample is also commercially available.

In high-resource settings, PCR-based detection of parasite DNA in stool or urine samples is also employed (Utzinger et al., 2015; McManus et al., 2018).

Tests for the detection of antibodies (e.g. Circumoval Precipitin Test [COPT] and Indirect Hemagglutination Assay [IHA]) are available but their use in regular practice is nowadays limited, notably as they cannot distinguish present and past infections, although they may still have a role in the case of travelers returning from endemic areas. In addition, they have been used to demonstrate absence of exposure to *Schistosoma* spp. in younger age groups living in formerly endemic areas, as a proxy for interruption of *Schistosoma* spp. transmission.

For detection of organ pathology, chest radiography can reveal pulmonary infiltrates in acute schistosomiasis, while imaging methods, such as ultrasound, computed tomography scan (CT scan), and Magnetic Resonance Imaging (MRI), can demonstrate evidence of chronic pathology such as liver fibrosis and portal hypertension in intestinal schistosomiasis, and urinary tract fibrosis, polyps, and ulcers in urinary schistosomiasis.

In endemic settings, ultrasound is often the only imaging resource and can be used both in clinical settings and in the context of population-based screening exercises, thanks to the availability of portable ultrasound machines; the use of abdominal and pelvic ultrasonography for the assessment of schistosomiasis-related morbidity of the liver and the urinary tract, respectively, has been standardized by WHO through the so-called Niamey protocol (Richter et al., 2016).

Testing for microhematuria (invisible, abnormal presence of blood in urine) using a reagent strip test is also commonly used in population-based surveys to estimate prevalence of *S. haematobium* infection or burden of morbidity in endemic areas. These surveys have been especially carried out among school-aged children, as in this population other causes of hematuria can usually be excluded, and therefore a correlation can be established between presence of blood in urine and *S. haematobium* infection (Utzinger et al., 2015).

Malacological techniques have largely been employed to detect *Schistosoma* spp. infection in the intermediate host snail, as a mean to demonstrate presence or absence of transmission in a given freshwater body. Traditionally, collection of intermediate host snails was followed by incubation or crushing of the snails to detect shedding of schistosome cercariae or presence of sporocysts, respectively. Such techniques are gradually being replaced by PCR-based methods or loop-mediated isothermal amplification (LAMP) assays that can detect prepatent or patent infection by demonstrating presence of sporocysts and cercariae in intermediate host snails, respectively. Recently, detection of DNA in the environment (eDNA; Alzaylaee et al., 2020) has been evaluated in some countries, and proven to be a promising technique for determining absence of schistosomes or their emergence. Malacological techniques are playing a growing role in demonstrating interruption of *Schistosoma* spp. transmission and therefore elimination of schistosomiasis from an endemic area.

Treatment

PZQ is an anthelmintic introduced in 1979; it is currently the treatment of choice against all the species of schistosomes affecting humans. WHO's recommendations are as follows: for adults and children over 4 years, by mouth, 40–60 mg/kg (Olliaro et al., 2011) as a single dose or using a dose pole, which calculates number of tablets according to the height of the individual (Montresor et al., 2005). Adverse events following treatment are usually minor and transient, although relatively frequent, especially in individuals harboring infections of heavy intensity. PZQ is marketed under different commercial names and the usual formulation is 600-mg tablets.

In the past, several antischistosomal pharmacological agents have been employed. Their use is nowadays rare because of lower efficacy and/or higher toxicity as compared to PZQ. Examples include hycanthone, metrifonate and oxamniquine against *S. haematobium* or *S. mansoni*, and niridazole and antimonials against *S. japonicum* (Kramer et al., 2014; Siqueira et al., 2017).

Chemotherapy aims at reducing and preventing burden of infection and associated morbidity, but does not prevent reinfection, although it has the potential to affect transmission at the community level through reduced egg output.

By decreasing the number of worms harbored by an individual (intensity of infection), chemotherapy reduces organ inflammation and pathology, and improves associated conditions such as anemia by limiting loss of blood in urine and stool

(WHO, 2006; Mduluzi et al., 2020). Through the same mechanism, chemotherapy can prevent the further development of chronic morbidity. Some authors have claimed that administration of PZQ is able to reverse or resolve existing organ fibrosis, but this finding requires further investigation (Nono et al., 2020).

Advanced stages of the disease cannot be treated by PZQ. Surgery may bring relief in severe cases of intestinal schistosomiasis, notably in case of hepatosplenic complications, through procedures such as ligation of esophageal varices, and porta-caval shunt surgeries. In urinary schistosomiasis, reconstructive surgery may be required in case of affected ureters. Ablative surgery, antineoplastic chemotherapy and radiotherapy are employed in the management of bladder cancer caused by schistosomiasis.

Prevention and control strategies

Preventive chemotherapy

Mass treatment with PZQ is the mainstay of WHO's strategy for public health control of schistosomiasis (WHO, 2006, 2012). Single-dose PZQ is administered at regular intervals to populations living in endemic areas, with a focus on children and young adults, among whom the highest levels of prevalence and intensity of *Schistosoma* spp. infections are usually found. Treatment, extended to wider population groups, should the program aim at decreasing and interrupting transmission. Frequency of treatment varies according to transmission levels and is usually 12–24 months.

The rationale of preventive chemotherapy lies in the fact that although a single administration would not kill 100% of the worms (especially in the case of individuals who have high-intensity infections), treatment at regular intervals will keep intensity of infection at low levels, thus preventing the development of morbidity; in addition, reducing the average number of worms harbored by infected individuals would consequently decrease the amount of eggs discharged in faeces and urines, thus reducing environmental contamination and impacting on overall transmission rates in the target area (Gabrielli et al., 2011).

Mass administration of PZQ to children under 4 years is challenging because of the lack of safety data in younger population groups and of the large size and bitter flavor of the tablet which may increase risk of choking (Kernell et al., 2018). Pediatric formulations of PZQ (Coulibaly et al., 2017) are under development to fill this gap and enable extending the target of mass treatment interventions, also considering that evidence has shown that very young children may already be infected and contribute to sustaining transmission (Montresor and Garba, 2017). Another challenge is associated with the continuous and extensive use of the drug, which may lead to PZQ-resistant strains of schistosomes (Crellen et al., 2016).

Snail control, access to water and sanitation and environmental management

Before the introduction of PZQ, snail control was widely used in schistosomiasis programs, with the aim of decreasing the population of snail intermediate hosts and the number of cercariae in water bodies, thus preventing the completion of the parasite's cycle, and limiting the chances of transmission to humans.

The release of chemicals, such as niclosamide, directly into water, is still the most commonly used approach to snail control and has been implemented in many endemic areas (King et al., 2015). Other approaches include the use of biological and ecological measures, including snail predators such as fish and crustacea (Lardans and Dissous, 1998).

Over the past 40 years, in many parts of the world, snail control programs have been gradually discontinued and competencies faded away, while the strategic focus moved toward preventive chemotherapy. Recently, however, WHO has recommended a multi-pronged approach and reintroduced snail control as an important public-health measure to complement mass treatment and sustain the public health impact of this core intervention. Snail control is specifically recommended as an essential intervention where the impact of preventive chemotherapy alone is less substantial than expected, and where low levels of transmission have been achieved and the public health goal moves from control of morbidity to interruption of transmission (WHO, 2017). This reflects the global commitment to elimination of schistosomiasis affirmed through the adoption of World Health Assembly resolution WHA65.21 (2012).

Snail control is part of wider efforts aimed at modifying the environmental conditions in which schistosomiasis thrives, namely through water supply and adequate sanitation, and environmental management such as removal of vegetation on which snails feed, lining canals with cement, or draining water bodies.

Health education

Health education and health promotion messages have an important role in prevention of schistosomiasis, notably in endemic countries (Price et al., 2015; Person et al., 2016). Primary preventive messages focus on discouraging unsafe water practices (e.g. bathing in contaminated ponds) and avoiding indiscriminate urination and defecation (to decrease environmental contamination). Secondary prevention encourages compliance with disease control interventions, notably mass treatment with PZQ. Social mobilization and sensitization on the public-health impact of schistosomiasis, its transmission cycle and the ways and means to tackle its burden are key activities that are regularly implemented in endemic communities.

Vaccines

Several vaccine candidates against schistosomiasis have been the subject of investigations over the past 40 years and have reached different stages of development; some of them are currently in various phases of human clinical trials (Tebeje et al., 2016). Candidate vaccines can be aimed at preventing morbidity (e.g. by eliciting protective immune responses that would lead to reduced worm burdens and decreased egg production) and/or infection (e.g. by limiting transcutaneous penetration of the cercariae).

The limited understanding of the complex interactions between the human host and parasites, including the mechanisms behind protective immunity has so far hampered the development of an effective vaccine for schistosomiasis. In principle, availability of a vaccine for animals would accelerate the reduction of the zoonotic transmission of the diseases (You et al., 2018).

The two most advanced vaccines which have undergone trials in humans are the Sh28GST and the Sm14. Both vaccines aim first to reduce morbidity due to schistosomiasis by decreasing fecundity of the worms, and secondarily to prevent reinfection. Administration of PZQ at the same time as the vaccine is recommended to boost the immune system and increase the production of antibodies. The Sh28GST vaccine went through human trials (Phase I to III). The phase III trial was conducted in an area endemic for *S. haematobium* in Senegal, and has shown no efficacy of the vaccine in protecting from reinfection (Riveau et al., 2018). Phase II trials of the Sm14 vaccine were conducted in Senegal in 2017 and 2018, and have shown a good tolerance and immunogenicity to both *S. haematobium* and *S. mansoni* (Tendler et al., 2018).

Due to the lack of an effective vaccine, vaccination is not currently included among the strategic approaches recommended by WHO to control and eliminate schistosomiasis.

Chemoprophylaxis

PZQ cannot be used for chemoprophylaxis because of its short half-life (1–1.5 h) and because it cannot kill schistosomula, the migrating larvae that are 3–21 days old. Artemether, a derivative of artemisinin which comes from the leaves of the medicinal plant *Artemisia annua*, is commonly used for the treatment of malaria, and has been shown to be effective against juvenile schistosomes during the first 21 days of infection in animals and humans (Elmorshedy et al., 2016). Accordingly, it has been used as a chemoprophylactic for high-risk groups, such as flood relief workers and fishermen, in areas where schistosomiasis is endemic. Although tested in several countries and against various *Schistosoma* spp. (Pérez del Villar et al., 2012), chemoprophylaxis with artemether is not commonly used outside China.

Treatment of animal reservoir

A wide range of mammals can be infected with schistosomiasis (Sobhon and Upatham, 1990; McManus et al., 2018; Gordon et al., 2019). The role of animals in sustaining transmission in endemic areas is debated. Bovines, however, and particularly water buffaloes (*Bubalus bubalis*), have been shown to play a major role in the transmission of *S. japonicum* in China. Periodic treatment of bovines with PZQ, managed by local veterinarians, is therefore often included in control programs for *S. japonicum* in that country (Li et al., 2015).

Progress and perspectives

In 2019, 105.4 million people received preventive chemotherapy with PZQ globally. Of them, 86.3 million were school-age children, and 19.1 million adults. Coverage among school-age children was 67.2%, while among adults it was 17.7%. Overall coverage was 44.5% (105.4 million out of 236.6 million). Treatments in the African region represented 86% of all those delivered globally (WHO, 2020).

In addition to scaling up treatment for populations in need, progress has also been made in several countries toward elimination as a public-health problem and elimination (interruption of transmission).

Elimination of schistosomiasis as a public health problem is defined by WHO as <1% proportion of heavy-intensity schistosomiasis infections in the population of the geographical under consideration, and has been achieved in several countries and areas (WHO, 2012, 2021).

Elimination of schistosomiasis is equivalent to its interruption of transmission, i.e. reduction of incidence of infection to zero. This achievement has been claimed by some formerly endemic countries on the basis of the absence of detection of cases by the surveillance system and of the results of population-based surveys in areas previously known to be endemic.

As of 2021, WHO lists several countries and territories in the categories “Interruption of transmission to be confirmed” and “Status of transmission to be determined” (Fig. 2; WHO, 2021): the health authorities of these countries usually consider their nations as free of transmission.

The 19 countries where interruption of transmission has to be confirmed include Algeria and Mauritius in the African region; Antigua and Barbuda, Dominican Republic, Guadeloupe, Martinique, Montserrat and Puerto Rico in the region of the Americas; Djibouti, Islamic Republic of Iran, Jordan, Lebanon, Morocco and Tunisia in the Eastern Mediterranean region; Turkey in the European region; India and Thailand in the South-East Asia region; Japan and Malaysia in the Western Pacific region.

The 7 countries where the status of transmission has to be determined include Saint Lucia and Suriname in the region of the Americas; and Iraq, Libya, Oman, Saudi Arabia and the Syrian Arab Republic in the Eastern Mediterranean region.

The list is closed by China (in the Western Pacific region), which is currently listed as endemic but not requiring preventive chemotherapy, bringing the number of countries with low levels of transmission to 27.

The new road map for neglected tropical diseases 2021–30 was endorsed by the Seventy-third World Health Assembly on 13 November 2020, through the adoption of decision WHA73(33), and officially launched on 28 January 2021. The road map lists schistosomiasis among the diseases targeted for elimination as a public health problem. The aim is to have all 78 countries still reporting schistosomiasis or where transmission is presumed to occur validated as having achieved this target by 2030 (WHO, 2021). WHO is currently in the process of establishing a formal acknowledgment process, in line with similar initiatives for other neglected tropical diseases.

Fig. 2 Status of countries and territories endemic for schistosomiasis, and proportion (%) of global population requiring preventive chemotherapy, 2019 (WHO, 2021).

Critical actions to achieve the above target set by the road map include implementing effective interventions, such as extending preventive chemotherapy to all populations in need by securing access to the necessary medicines; improving the arsenal of diagnostic tests, especially those suitable to low-transmission areas; creating cross-sectoral governance mechanisms to coordinate the fully-fledged implementation of all strategic approaches; and ensuring availability of sufficient resources to enable the above steps (WHO, 2021).

Introduction

Soil-transmitted helminths belonging to the genus *Strongyloides* (*Strongyloides fuelleborni* and the more prevalent *Strongyloides stercoralis*) are currently believed to infect an estimated 30–100 million people worldwide.

Infection caused by *Strongyloides* is the most neglected of neglected tropical diseases, despite that the global burden is significant (Olsen et al., 2009).

The disability-adjusted life year (DALY) estimation is complicated for *Strongyloides* infection, because of the absence of any clinical markers that can be easily monitored during the follow-up and the evident limitations in identifying the uninfected control groups with the poor sensitive direct diagnostic tools available (Krolewiecki et al., 2013).

The most severe effects of strongyloidosis occur in patients receiving immunosuppressive therapy with corticosteroids; disseminated infection may lead to life-threatening conditions with pneumonia, septicemia and intestinal obstruction with a mortality rate of 98% (Olsen et al., 2009).

Systematics

The genus *Strongyloides* (nematoda: Rhabditida) comprises more than 50 gastrointestinal parasitic nematode species. In humans, *S. stercoralis* is the major causative agent of strongyloidosis. Rarer human-infecting species of *Strongyloides* are the zoonotic.

S. fuelleborni (*fuelleborni*) subsp. *fuelleborni* and *S. fuelleborni* subsp. *kellyi*, for which the only currently known host is humans (CDC, DPDx homepage). While *S. stercoralis* has a cosmopolitan distribution, mainly in tropical and sub-tropical regions, human infection with *S. fuelleborni fuelleborni* only occurs sporadically in Africa and the Southeast Asian country of Papua New Guinea (Korenaga and Bruschi, 2014). Recently, a molecular phylogenetic analysis using nuclear and mitochondrial markers indicated the presence of two distinct lineages of *S. stercoralis* (referred to as type A and type B), respectively clade I and clade II, subdivided in different haplotypes groups. While type A parasites were isolated both from humans and dogs in different endemic countries, type B parasites were found exclusively in dogs. The 18S rDNA hyper-variable region I (HVR-I) analysis differentiated human and dog strains (Nagayasu et al., 2017).

Life cycle

The life cycle of *S. stercoralis* is unique, alternating between free-living and parasitic cycles and involving autoinfection (CDC, DPDx homepage). A range of vertebrate hosts, including humans and dogs, become infected when free-living infective larvae (L3i) penetrate the skin, facilitated by their dispersal and nictation behaviors (Little, 1966). The larvae migrate into the lungs via the bloodstream, pass the capillary walls, reach the alveoli, bronchus and trachea, where they are swallowed and end up in the small intestine. The larvae molt twice and become adult female worms. The sizes are 2.1–2.7 (2.4 in average) mm in length and 30.0–40.0 (37.0) mm in width. In the small intestine submucosa the females produce eggs via parthenogenesis, from which rhabditiform larvae (L1i) hatch, pass through the gut of the host with feces and develop in the external environment.

Streit (2008) reviewed the literature on the modes of reproduction and development of *Strongyloides*. Parthenogenesis, probably, is the most common mode of reproduction in parasitic females of *Strongyloides*. Cytological studies revealed that no meiosis occurred during oogenesis in the parasitic females; Viney (1994) demonstrated that all individuals of the progeny were genetically identical, resulting in a mitotic reproduction.

The development of the L1i can take two alternative life cycles: indirect (heterogonic) and direct (homogonic). In the indirect cycle L1 larvae develop via L2–L4 to free-living male and female adults, reproduce offspring and release L1i which molt into filariform L3 (infective stages). Infective L3 stages are long lived and persist in the environment until they encounter a suitable host (Little, 1966). In the direct cycle rhabditiform larvae (female) have the alternative fate to molt twice via an L2 into infective L3i. L3i are threadlike in shape (filariform), 490–630 (563) mm in length, and 15–16 (15.8) mm in width in *S. stercoralis*.

Genetic background of *Strongyloides* isolates and host factors affect the sex ratio and the homogonic versus heterogonic switch. Temperature and host immune response affect the two alternative developmental switches. It has been demonstrated that the increase of the host immune response induces females to undergo the heterogonic development. Matoff (1936) and Graham (1939) demonstrated also a seasonal dependent variation in the life-cycle 'choice,' such that in summer both development cycles occurred, whereas in winter only the homogonic cycle occur. The ratio of homogonically to heterogonically developing females was demonstrated to be altered during experimental transfer to different host species in *S. stercoralis* and *S. fuelleborni*. Interestingly, Crook et al. (2005) showed a reduction of the proportion of free-living adults of both sexes during the transfer of *S. ratti* into the atypical murine host, acting as non-immunological stressor.

Autoinfection is possible when L1 larvae transform within the intestine into L3i (Korenaga and Bruschi, 2014). They penetrate either the intestinal mucosa (internal autoinfection) or perineal skin area (external autoinfection), complete their maturation in adults and give rise to a generation of worm females.

Interestingly, *S. fuelleborni* produces eggs which are shed in the feces, although hatched rhabditiform larvae may be found if fixation and processing are delayed. They are slightly ovoid (50–60 × 30–40 mm) with a thin, colorless shell, and are passed partially embryonated.

Strongyloidosis has been considered potentially zoonotic because dogs may also serve as definitive hosts; some authors supported the idea of a possible cross-transmission of *Strongyloides* between humans and dogs (Shoop et al., 2002; Thamsborg et al., 2017), whereas studies from Takano and collaborators excluded any relationship between human and canine strongyloidosis in endemic areas. In dogs, an eventual transmammary transmission has been demonstrated for several species of *Strongyloides*, except for *S. stercoralis* (Takano et al., 2009).

The life cycle of *S. stercoralis* is shown in Fig. 1.

Immune response and pathogenesis
